In an RCT, 189 men with both erectile dysfunction and LUTS (defined as IPSS ≥12) received 50 mg sildenafil once daily for 2 weeks, further increased to 100 mg for a total of 12 weeks of treatment (McVary et al., 2007a); **the IPSS decreased by a mean of 6.32 points from the baseline after sildenafil therapy as compared with a decrease of 1.93 points in the placebo group ($P < 0.0001$).** Men with severe LUTS showed the higher benefit from treatment (–8.6 points compared with –2.4 points in the less severely symptomatic men). No differences were reported in terms of changes in urinary flow parameters between groups. The same authors performed a second RCT, which included 281 men with LUTS/BPH treated either with placebo or with 5 mg tadalafil once daily for 6 weeks, followed by a dose escalation to 20 mg for an additional 6 weeks (McVary et al., 2007b). At the end of treatment, the IPSS decreased by 3.8 points in the tadalafil group compared with 1.7 points in the placebo group. They also observed a significantly greater decrease of the IPSS QoL score and the BII. **Men in the tadalafil group were more likely to show a 3-point or greater decrease in the IPSS by 12 weeks than those in the placebo group (60.9% vs. 42.7%).** As for the sildenafil trial, changes in the uroflowmetry parameters were not significant on assessment at 12 weeks. Overall, AEs commonly associated with tadalafil treatment were observed, with 2.2% of patients reporting dyspepsia, back pain, and headache.

Likewise, the effect of vardenafil on LUTS was assessed in an RCT including men with an IPSS of 12 or greater treated with 10 mg vardenafil twice daily or placebo (Stief et al., 2008). **The IPSS significantly decreased after 8 weeks of treatment, with a greater decrease in the vardenafil group (–5.9 vs. –3.6; $P = 0.001$)**; the decrease was significant for both the storage subscore and the voiding subscore. Headache, dyspepsia, and flushing were the most commonly observed AEs, reported by 13%, 7.4%, and 6.5% of patients, respectively.

Because of its longer half-life and convenient 5-mg daily dose, **tadalafil has been the most widely assessed PDE5I in patients with LUTS,** resulting in it being the only drug currently licensed as an on-label treatment for male LUTS. Roehrborn et al. (2008b) performed a dose-finding trial that enrolled 1058 men with LUTS who were randomly allocated to receive either placebo or tadalafil at 2.5, 5, 10, or 20 mg once daily for 12 weeks. All tadalafil doses resulted in a significant decrease of the IPSS as compared with placebo, with a clear dose-response effect (Fig. 145.13). Moreover, all doses were well tolerated, although the rate of patients reporting at least one AE increased with increasing doses; overall, the 5-mg dose provided the best risk-benefit profile. The efficacy of tadalafil therapy in patients with LUTS was confirmed in other well-conducted RCTs (Egerdie et al., 2012; Oelke et al., 2012; Porst et al., 2009, 2011) and by three meta-analyses (Brock et al., 2013; Porst et al., 2013a, 2013b). Overall, 5 mg tadalafil once daily has been shown to reduce both the total IPSS and the QoL score by 6 and 1 points compared with 3.6 and 0.7 points for placebo ($P >$ 0.001) (Hatzimouratidis, 2014). There was no significant differences in the magnitude of the effect among patients with and without erectile dysfunction at the baseline, thus suggesting that drug efficacy is not related to an indirect effect involving psychological benefit associated with erectile function improvement (Brock et al., 2013).

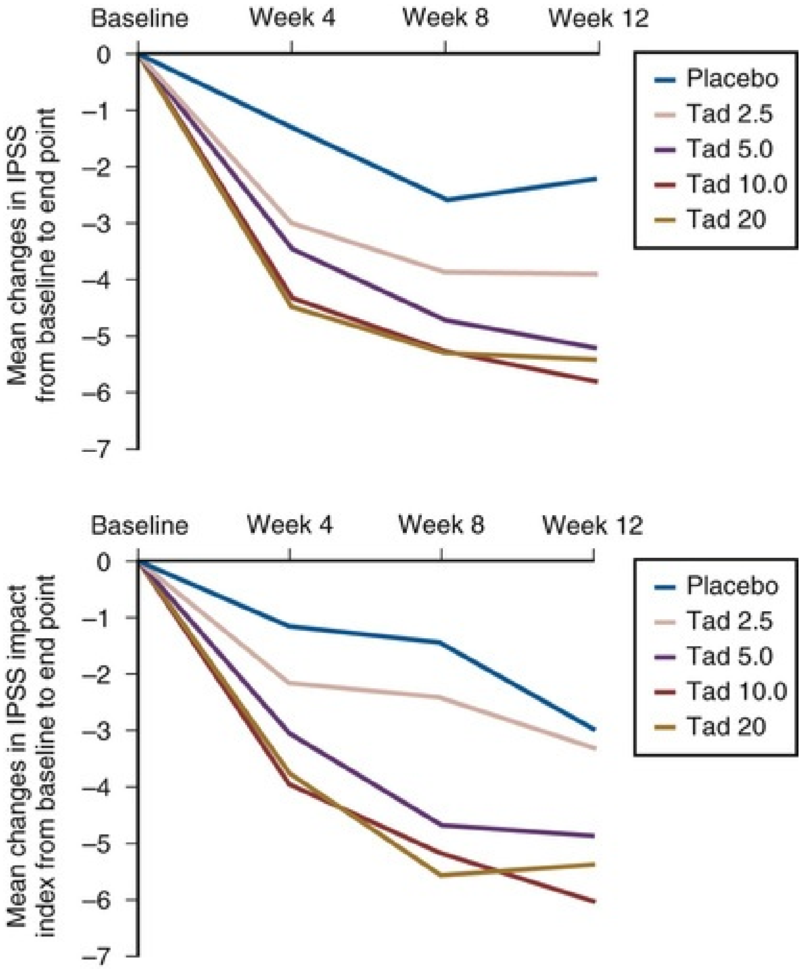

FIG. 145.13 Response of lower urinary tract symptoms to tadalafil. Mean change in International Prostate Symptom Score (IPSS) and Benign Prostatic Hyperplasia Impact Index after treatment with placebo or tadalafil

(Tad) at 2.5, 5, 10, and 20 mg/day. (From Roehrborn CG, McVary KT, Elion-Mboussa A, et al. Tadalafil administered once daily for lower urinary tract symptoms secondary to benign prostatic hyperplasia: a dose finding study. *J Urol* 180[4]:1228–1234, 2008b.)

Urodynamic studies, and meta-analyses of RCTs did not report a significant impact of tadalafil in terms of urodynamic and uroflowmetry parameters (Dmochowski et al., 2010; Dong et al., 2013).

Gacci et al. (2016b) summarized data from eight systematic reviews and meta-analyses concerning the use of PDE5Is in men with BPH and from nine studies reporting post hoc pooled data analyses of patients with LUTS treated with 5 mg tadalafil versus placebo. Their findings confirmed the efficacy of PDE5Is in terms of IPSS reduction, without significant effects on uroflow parameters; moreover, they showed that PDE5Is are overall well tolerated. Pooled data on 5 mg tadalafil compared with placebo showed clinically significant relief of urinary symptoms and reduction of nocturnal voiding frequency.

Dahm et al. (2017) recently reviewed the results of trials comparing tadalafil alone with α_1-blockers for the treatment of LUTS. In four 3-month trials comparing tadalafil with tamsulosin, both drugs caused a similar reduction of mean total IPSS and QoL score. Similarly, in two trials comparing tadalafil with alfuzosin, both drugs caused a significant IPSS reduction, although the mean change from baseline was greater in the alfuzosin group (4.1 vs. 7.2).

Similar results emerged from pooled data analyses of trials comparing sildenafil with alfuzosin, doxazosin, or tamsulosin (Dahm et al., 2017).

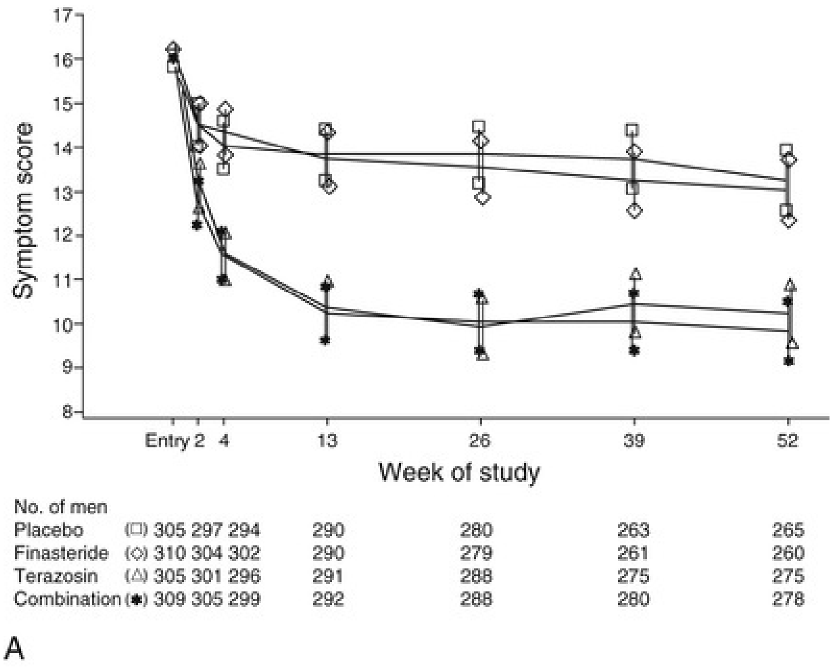
International clinical guidelines currently suggest PDE5Is as an alternative therapy for men with moderate to severe LUTS, with or without associated erectile dysfunction (Abrams et al., 2013; Oelke et al., 2013)**. Tadalafil is currently the only officially licensed PDE5I for the treatment of male LUTS. The recommended dose is 5 mg taken at approximately the same time every day with or without food.**

Combination Therapy for Lower Urinary Tract Symptoms

α-Adrenergic Blockers and 5α-Reductase Inhibitors

To date, five RCTs have assessed the efficacy of combination therapy of α_1-blockers and 5ARIs for LUTS (Debruyne et al., 1998; Kirby et al., 2003; Lepor et al., 1996; McConnell et al., 2003; Roehrborn et al., 2008a). **Of those, only the MTOPS study and the Combination of Avodart and Tamsulosin (CombAT) study reported results at follow-up longer than 1 year.**

In the Veterans Affairs Cooperative Study, Lepor et al. (1996) evaluated 1229 men with symptomatic BPH, a PFR below 15 mL/s and a PVR volume lower than 300 mL who had been randomized to receive placebo, finasteride, terazosin (titrated from 1 to 10 mg), or a combination of both active compounds for 52 weeks. There was a greater significant reduction of the AUASI scores in the terazosin group (6.1 points) and the combination therapy group (6.2 points) compared with the finasteride group (3.2 points) and the placebo group (2.6 points) (Fig. 145.14A). Similarly, changes in PFR were significant only for the terazosin and the combination therapy groups (see Fig. 145.14B). PV decreased by approximately 20% in the finasteride and combination therapy groups. The authors concluded that the combination therapy was not more effective than terazosin alone in treating patients with LUTS/BPH. Of note, the mean PV in all treated arms was lower than 40 mL.



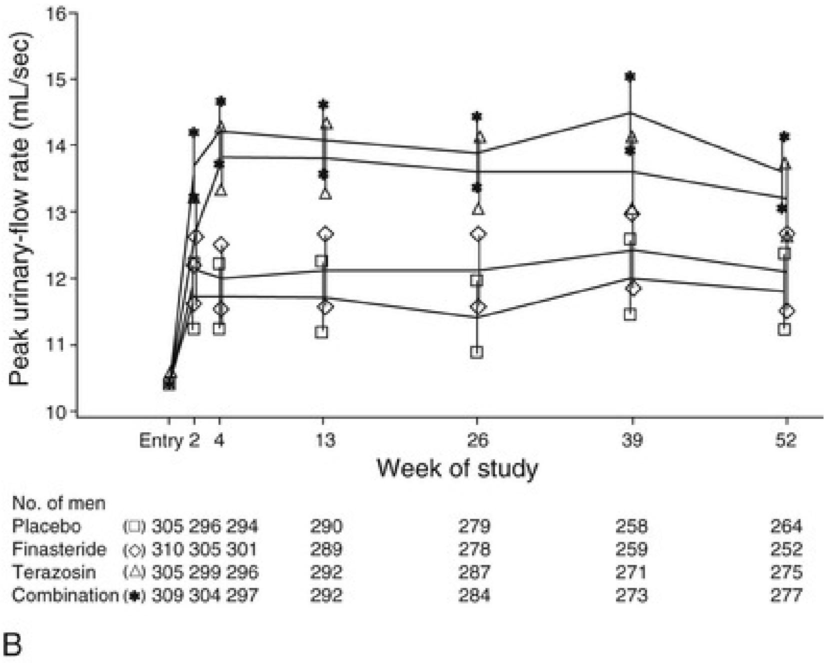


FIG. 145.14 (A) AUA Symptom Scores in men with BPH, according to treatment group. Scores are expressed as adjusted means and the 95% confidence interval *(CI).* The results of primary pairwise comparisons are as follows: finasteride and terazosin, $P < 0.001$; finasteride and combination therapy, $P < 0.001$; and terazosin and combination therapy, $P = 1.00$. The results of secondary pairwise treatment comparisons are as follows: finasteride and placebo, $P = 0.63$; terazosin and placebo, $P < 0.001$; and combination therapy and placebo, $P < 0.001$. (B) Peak urinary flow rates in men with BPH, according to treatment group. Rates are expressed as adjusted means and the 95% CI. The results of primary pairwise comparisons are as follows: finasteride and terazosin, $P < 0.001$; finasteride and combination therapy, $P < 0.001$; and terazosin and combination therapy, $P= 0.15$. The results of secondary pairwise treatment comparisons are as follows: finasteride and placebo, $P= 0.07$; terazosin and placebo, $P < 0.001$; and combination therapy and placebo, $P < 0.001$. (From Lepor H, Williford WO, Barry MJ, et al. The efficacy of terazosin, finasteride, or both in benign prostatic hyperplasia. Veterans Affairs Cooperative Studies Benign Prostatic Hyperplasia Study Group. *N Engl J Med*;335[8]:533–539, 1996. Figure 1, p. 536; Figure 2, p. 537.)

The Alfuzosin, Finasteride and Combination study enrolled 1051 patients from several centers in Europe (Debruyne et al., 1998). Patients were randomized to receive 5 mg alfuzosin twice daily, 5 mg finasteride, or combination therapy for 6 months. Both patients treated with alfuzosin alone and patients treated with combination therapy showed significantly greater IPSS decreases as compared with those treated with finasteride alone. The rates of patients with at least a 50% IPSS decrease were 43%, 42%, and 33% in the alfuzosin, combination therapy, and finasteride groups, respectively.

Similar findings were also reported by the Prospective European Doxazosin and Combination Therapy (PREDICT) study, which enrolled 1095 patients randomized to receive either doxazosin (titrated from 4 to 8 mg), 5 mg finasteride, placebo, or combination therapy (Kirby et al., 2003). The doxazosin and the combination therapy groups both showed a significantly greater change of the IPSS from the baseline compared with the placebo and finasteride groups. Similar results were reported regarding PFR changes among different groups.

Medical Therapy of Prostatic Symptoms Trial

The previously discussed studies did not show an advantage of either 5ARIs or combination therapy in relieving symptoms and improving uroflowmetry parameters as compared with the first-line α_1-blocker treatment. However, all of them were designed to assess treatment outcomes after only 6 to 12 months of therapy. The MTOPS trial is a multicenter RCT aimed at assessing the outcomes of both monotherapy with doxazosin or finasteride and combination therapy over a period of no less than 4 years (McConnell et al., 2003). The primary aim of the MTOPS trial was to assess the risk for clinical progression, defined as occurrence of the following:

- 4-point or greater increase from baseline of the AUASI score
- AUR
- Recurrent UTIs (defined as two or more episodes within 1 year or urosepsis)
- Self-reported urinary incontinence
- Renal insufficiency (defined as an increase in serum creatinine level of at least 1.5 mg/dL or a 50% relative increase from the baseline)

Regarding the inclusion criteria, there were no restrictions related to PV, thus leading to the enrollment of patients with a wide difference in gland volumes. A total of 3047 men were enrolled and were randomized to receive 5 mg finasteride and placebo, doxazosin (titrated from 1 to 8 mg) and placebo, a combination of doxazosin plus finasteride, or two placebo drugs.

Four years after therapy had begun, the cumulative incidence of clinical progression was 17% in the placebo group, 10% in the doxazosin group, 10% in the finasteride group, and 5% in the combination therapy group (Fig. 145.15 and Table 145.15). **Both doxazosin and finasteride were significantly more effective than placebo in reducing the risk for clinical progression; moreover, combination therapy was even more effective than monotherapy.** The number of events per year was reduced by 39%, 34%, and 66% for doxazosin, finasteride, and combination therapy, respectively, compared with placebo. The authors showed that after both placebo and doxazosin treatment, the risk for clinical progression increased with increasing baseline PSA level and PV. **With regard to the specific events, the risk for AUR was significantly lower than with placebo only for the combination therapy and finasteride groups** (Fig. 145.16). Similarly, the authors looked at the occurrence of invasive therapy for BPH (open, endoscopic, or minimally invasive surgery) and estimated the cumulative incidence over time in the four groups. **Compared with placebo, both finasteride and combination therapy reduced the risk for receiving invasive therapy by 64% and 67%, respectively (*P* < 0.001)** (see Fig. 145.16). **Conversely, a similar result was not observed in the doxazosin group.**

FIG. 145.16 Cumulative incidence of (A) acute urinary retention and (B) invasive therapy for benign prostatic hyperplasia in the Medical Therapy of Prostatic Symptoms (MTOPS) trial. (From McConnell JD, Roehrborn CG, Bautista OM, et al. The long-term effect of doxazosin, finasteride, and combination therapy on the clinical progression of benign prostatic hyperplasia. *N Engl J Med* 349[25]:2387–2398, 2003.)

Secondary outcomes were changes over time of AUASI score, PFR, total PSA level, and PV; **a reduction of the AUASI score was observed over time in all active treatment groups compared with placebo, with a greater reduction found in the combination therapy group compared with the doxazosin group (7.4 vs. 6.6) and the finasteride group (7.4 vs. 5.6). Similarly, PFR increased in all groups.**

The number needed to treat to prevent clinical progression in the overall population was 8.4 for the combination therapy group but 13.7 and 15 for the doxazosin group and the finasteride group, respectively. **In the combination therapy group, these numbers dropped to 4.7 and 4.9 when patients with a baseline PSA level greater than 4.0 ng/mL and a PV greater than 40 mL were considered, suggesting that this strategy is an economically stronger option in patients at higher risk for progression.**

In terms of tolerability, **the overall rate of AEs was significantly higher in the combination therapy group as compared with both the placebo group and the monotherapy groups. However, the rates of each individual side effect were similar to those observed in the monotherapy groups.** In a recent re-evaluation of safety data from the MTOPS study, the rates of both sexual function–related AEs and other AEs appeared to be higher throughout the first year of treatment and decreased thereafter (Kaplan et al., 2016).

Combination of Avodart and Tamsulosin Study

The 4-year CombAT trial was designed with the primary aim of investigating whether the combination of dutasteride and tamsulosin was more effective than monotherapy in reducing the risk for AUR and BPH-related surgery (Roehrborn et al., 2008a). The inclusion criteria for the CombAT study were somewhat different from those of the MTOPS trial. Indeed, **to assess the effect of combination therapy on patients at high risk for BPH clinical progression, only men with a PV of 30 mL or greater and a serum PSA level of 1.5 ng/mL or greater were included.** As for the MTOPS trial, patients were 50 years or older and had an IPSS of 12 or greater and a PFR of 5 to 15 mL/s. Patients were randomized to receive either 0.5 mg dutasteride once daily plus placebo, or 0.4 mg tamsulosin once daily plus placebo or tamsulosin plus dutasteride for 4 years. As secondary outcomes, the risk for BPH clinical progression (as defined in the MTOPS trial), changes in IPSS, PFR, or PV; and the rate of AEs were recorded. A total of 4844 men were initially randomized, and 66% of them reached the end of treatment at 48 months. **There was a greater risk reduction for AUR and BPH related–surgery both for men treated with the combination therapy and for men treated with dutasteride monotherapy compared with men treated with tamsulosin monotherapy** (Table 145.16). Treatment with both drugs reduced the risk for AUR by 65.8% as compared with treatment with tamsulosin alone. The risk for AUR in the tamsulosin arm started to be significantly higher from 8 months afterward (Fig. 145.17). The risk for BPH surgery was reduced by 67.6% in the combination therapy group compared with the tamsulosin group (*P* < 0.001).

FIG. 145.17 Kaplan-Meier estimates of the time to the first episode of acute urinary retention or benign prostatic hyperplasia–related prostatic

surgery. (From: Roehrborn CG, Siami P, Barkin J, et al. The effects of combination therapy with dutasteride and tamsulosin on clinical outcomes in men with symptomatic benign prostatic hyperplasia: 4-year results from the CombAT study. *Eur Urol* 57[1]:123–131, 2010. Figure 3, p. 126.)

Combination therapy was superior than both monotherapies in reducing the risk for BPH clinical progression. In terms of symptom relief, patients in the combination therapy group reported a significant 7.3-point reduction of the IPSS after 4 years compared with reductions of 4.9 and 6.4 points for the tamsulosin and dutasteride groups, respectively ($P < 0.001$). These data confirmed the superiority also of dutasteride monotherapy over tamsulosin in terms of symptom relief at long-term follow-up; similar results were observed for PFR, thus suggesting that dutasteride could be more effective than tamsulosin at long-term follow-up. Further analyses showed that combination therapy was more effective than tamsulosin therapy alone in reducing both voiding and storage subscores (Montorsi et al., 2011).

Men with a baseline gland volume of 40 mL or greater showed the greater reduction in terms of the risk for AUR and BPH-related surgery both with combination therapy and with dutasteride monotherapy compared with tamsulosin monotherapy.

In terms of safety, the occurrence of AEs was higher in the combination therapy group relative to the monotherapy groups. However, withdrawal rates caused by drug-related AEs were comparable between the groups.

Overall, both the MTOPS trial and the CombAT trial support the therapeutic advantage of the combination of 5ARIs and α_1-blockers to treat patients with moderate to severe LUTS at high risk for BPH clinical progression (PV ≥ 30 to 40 mL and PSA level ≥1.5 ng/mL) as now suggested by international guidelines (Abrams et al., 2013; Oelke et al., 2013). The two drugs can be safely administered once daily at the usual dose recommended for monotherapy.

According to the results of the Symptoms Management After Reducing Therapy (SMART) trial, use of α_1-blockers may be discontinued after 6 months of successful combination therapy without symptom deterioration being expected (Barkin et al., 2003).

α-Adrenergic Blockers and Anticholinergic Receptor Blockers

Combination therapy with antimuscarinics and α_1-blockers in patients with BPH has been evaluated in several trials (Table 145.17). Kaplan et al. (2006) performed a multicenter RCT that enrolled 879 patients with an IPSS greater than 12 and significant storage symptoms reported over the previous 3 months (Kaplan et al., 2006). Patients were treated with tolterodine ER formulation at 4 mg/day, tamsulosin at 0.4 mg/day, tolterodine in combination with tamsulosin, or placebo for a total of 12 weeks. **The primary end point of the study was patients' perception of treatment benefit at the end of the treatment course as measured with a single-item question (the Perception of Treatment Benefit question). The rate of patients reporting a treatment benefit was significantly higher in the combination therapy group (80%) compared with the placebo group. The findings were neither comparable for the tolterodine-alone group or for the tamsulosin-alone group.** Moreover, patients in the combination therapy group showed a significant reduction in urgency episodes, daily and nightly number of micturitions, and total IPSS and QoL scores (Fig. 145.18). Urinary flow and PVR volume did not differ among the groups. Only two patients (0.4%) treated with tamsulosin plus tolterodine reported an episode of AUR.

FIG. 145.18 (A and B) Response of lower urinary tract symptoms to tolterodine, tamsulosin, or combination therapy versus placebo. *ER,* Extended release; *IPSS,* International Prostate Symptom Score. (From Kaplan SA, Roehrborn CG, Rovner ES, et al. Tolterodine and tamsulosin for treatment of men with lower urinary tract symptoms and overactive bladder: a randomized controlled trial. *JAMA* 296[19]:2319–2328, 2006.)

In a previous multicenter randomized trial, 198 patients with urodynamically proven BOO and OAB symptoms were treated with 4 mg doxazosin once daily versus 20 mg propiverine combined with 4 mg doxazosin daily for 8 weeks (Lee et al., 2005). The combination therapy group showed more favorable outcomes in terms of urinary frequency reduction, average micturition volume, and IPSS (see Table 145.17). There was a significant increase in PVR volume (20.7 mL) with the combined therapies, without any case of AUR. The overall rate of AEs was higher for patients receiving both drugs, although discontinuation because of AEs was not different between the groups.

The combination therapy of propiverine plus naftopidil was compared with monotherapy with either naftopidil or propiverine for 4 weeks in a randomized study with men reporting symptomatic BPH and storage symptoms (Yokoyama et al., 2009). There was a significant reduction in terms of IPSS and urinary frequency episodes in the group of patients receiving both compounds (see Table 145.13). More recently Matsukawa et al. (2017) reported the results of a randomized trial comparing the efficacy of the combination of silodosin and propiverine compared with silodosin alone in 120 patients with BPH and storage symptoms. Patients in the combination therapy group showed a significantly greater reduction in the OABSS and urgency score after 1 year of treatment. Moreover, the presence of DO disappeared in 54.5% of patients after combination therapy as compared with 34.2% of patients after monotherapy.

The effect of sequential combined therapies has been investigated as an approach that better mirrors what is likely to happen in real-life clinical practice; according to this therapeutic paradigm, only patients not responding to α_1-blockers may deserve treatment with an antimuscarinic in addition to the first drug. MacDiarmid et al. (2008) performed a multicenter double-blind study that enrolled 420 men with symptomatic BPH and IPSS storage subscore of 8 or greater treated with a 4-week course of tamsulosin without benefit. Patients were randomized to receive tamsulosin plus oxybutynin once daily or tamsulosin plus placebo for 12 weeks. Patients receiving the combination treatment showed a significantly greater reduction in all symptom scores, without any difference in terms of PFR and PVR volume (see Table 145.17). Chapple et al. (2009) reported findings of a double-blind trial including men complaining of frequency, urgency, and at least one moderate issue reported with the Patient Perception of Bladder Condition (PPBC) despite taking a stable α_1-blocker dose for at least 1 month. Patients were thus randomized to receive a 4-mg tolterodine ER formulation once daily or placebo in addition to the same α_1-blocker for 12 weeks. There was a reduction in the number of 24-hour micturition and urgency episodes and nocturnal urgency episodes in the tolterodine group compared with the placebo group. Moreover, in a double-blind trial that tested solifenacin add-on therapy in patients with residual OAB symptoms after tamsulosin therapy, a significant reduction in terms of urgency episodes was observed for the combination therapy group compared with the placebo plus tamsulosin group (Kaplan et al., 2009).

Finally, the results of the phase II (SATURN) and phase III (NEPTUNE) trials assessing the effect of a novel drug formulation combining solifenacin with an oral controlled-absorption system (OCAS) formulation of tamsulosin were recently reported (Drake et al., 2015; Van Kerrebroeck et al., 2013a, 2013b). A total of 1334 patients with IPSS of 13 or greater, two or more urgency episodes daily, and eight or more micturition episodes per day were randomized to receive a single tablet of 6 or 9 mg solifenacin plus OCAS tamsulosin, monotherapy with OCAS tamsulosin, or placebo for 12 weeks. The combination treatment led to a significant reduction of both storage and voiding symptom scores and QoL scores as compared with placebo; moreover, patients with moderate to severe LUTS receiving solifenacin plus tamsulosin showed greater reductions of storage symptom and QoL scores as compared with patients receiving tamsulosin alone. The open-label extension trial (52 weeks) confirmed the efficacy of the new single tablet formulation and a good safety profile, with only 0.7% of patients reporting an episode of AUR. Of note, as in the other trials assessing the effect of antimuscarinics in BPH patients, only men with low (<150 mL) baseline PVR volume were included in the study.

Overall, the combination of antimuscarinics and α_1-blockers appears safe and effective in patients with persisting storage symptoms after first-line treatment with α_1-blockers. Dose adjustment is not required when adding antimuscarinic drugs to α_1-blockers therapy. However, the profile of patients who would benefit more from a combination treatment has not yet been clarified.

α-Adrenergic Blockers and β_3-Agonists

The advantage of combining mirabegron with α_1-blockers to treat LUTS/BPH was recently assessed in a few studies (Ichihara et al., 2015; Matsuo et al., 2016; Wada et al., 2016). In a prospective trial with patients older than 65 years of age with persistent LUTS and OAB symptoms after a course of therapy with an α_1-blocker for more than 12 weeks, the effect of 3-month add-on therapy with mirabegron was evaluated with use of the OABSS and the IPSS (Matsuo et al., 2016). There was a significant reduction of OABSS (from 6 to 4.4), total IPSS (from 15.1 to 11.8), and IPSS QoL score (from 4.2 to 3.4) at the end of treatment, and a PFR increase (4 mL/s) without a significant PVR volume modification was also observed. Similar findings were reported, even in a small prospective study evaluating the combination of mirabegron and tamsulosin in 26 men with persisting OAB symptoms after α_1-blocker monotherapy (Wada et al., 2016). Patients were assessed with PFS at the baseline and after the combination therapy, with no significant changes of the bladder contractility index being shown.

Ichihara et al. (2015) performed the only randomized trial investigating the effect of a combination of mirabegron and tamsulosin. The study enrolled 94 patients with LUTS most likely secondary to BPH and persistent OAB symptoms after a therapy course of at least 8 weeks with 0.2 mg tamsulosin. Patients were randomized to receive either 0.2 mg tamsulosin once daily alone or tamsulosin plus 50 mg mirabegron daily for 8 weeks. There was a significant reduction of the total OABSS during the treatment period, which was greater for the combination therapy group compared with the monotherapy group (–2.21 vs. –0.87; $P = 0.01$). Moreover, patients treated with mirabegron plus tamsulosin showed a greater reduction of IPSS storage subscore (–2.03 vs. –0.42), daytime frequency (–0.76 vs. –0.05), and IPSS QoL score (–0.76 vs. –0.05). In terms of safety, a significant PVR volume increase was observed in the combination therapy group, but only one patient reported urinary retention.

Overall these data suggest that mirabegron can be safely added to a treatment with α_1-blockers in patients with persisting storage symptoms. Dose adjustment is not required because mirabegron has no interactions with α_1-blockers. Further data are needed to confirm the benefit of this combination therapy.

α-Adrenergic Blockers and Phosphodiesterase Type 5 Inhibitors

Therapy with PDE5Is alone was demonstrated to significantly relieve LUTS compared with placebo. In this context, the effect of a combination therapy of PDE5Is and α_1-blockers has been assessed (Table 145.18). Kaplan et al. (2007) performed a randomized trial including 62 patients with previously untreated LUTS and erectile dysfunction treated with either alfuzosin, sildenafil, or the combination of both for 12 weeks. At the end of the treatment course, the **IPSS was significantly reduced in both groups, but the magnitude of the reduction was greater for the combination therapy group (–24.1%) than for either the alfuzosin group (–15.6%) or the sildenafil group (–16.9%). A significant increase in PFR and decrease in PVR volume was observed after alfuzosin and combination therapy, whereas uroflowmetry parameters did not change after sildenafil monotherapy.** The combination therapy was well tolerated, with no hypotension or syncope events during the 3 months of treatment. Conversely, in a trial randomizing 60 patients with LUTS to receive an 8-week course of sildenafil therapy alone, tamsulosin therapy alone or the combination of the two, IPSS reduction was not significantly different between the combination therapy group and the tamsulosin monotherapy group (Tuncel et al., 2010).

TABLE 145.18

Randomized Trials Assessing Combination Therapy of Phosphodiesterase Type 5 Inhibitors and α-Blockers

	DRUG	PATIENTS	LENGTH OF TREATMENT	SYMPTOMS (IPSS TOTAL: WEIGHTED DIFFERENCE BETWEEN DRUGS [95% CI])	PEAK RATE (WEI DIFF BETW DRUG CI])
Kaplan et al., 2007	Alfuzosin 10 mg Sildenafil 25 mg daily Alfuzosin + sildenafil	*N* = 37 Mean IPSS 17.3	12 weeks	α-Blocker alone vs. combination therapy: –1.1 (–3.5 to 1.3)	α-Blocker combinati therapy: 1 2.6)
Bechara et al., 2008	Tamsulosin 0.4 mg Tadalafil 20 mg daily Tamsulosin + tadalafil	*N* = 27 Mean IPSS 19.4	12 weeks	α-Blocker alone vs. combination therapy: –2.5 (–5.7 to 0.7)	α-Blocker combinati therapy: 3.6)
Liguori et al., 2009	Alfuzosin 10 mg Tadalafil 20 mg daily Alfuzosin + tadalafil	*N* = 39 Mean IPSS 15	12 weeks	α-Blocker alone vs. combination therapy: –1.5 (–3.7 to 0.7)	α-Blocker combinati therapy: 1 3.2)
Tuncel et al., 2010	Tamsulosin 0.4 mg Sildenafil 25 mg 4/week Tamsulosin + sildenafil	*N* = 40 Mean IPSS 15.4	8 weeks	α-Blocker alone vs. combination therapy: 0.0 (–1.8 to 1.8)	α-Blocker combinati therapy: 5.9)
Gacci et al., 2012b	Tamsulosin 0.4 mg Vardenafil	*N* = 59 Mean IPSS	12 weeks	α-Blocker alone vs. combination therapy: –3.8 (–4.3	α-Blocker combinati therapy: 1

	10 mg daily Tamsulosin + vardenafil	19.6		to –3.2)	1.9)

[a] The most common adverse events are reported if available.

IPSS, International Prostate Symptom Score; *NR,* not reported; *NS,* not significant; *PFR,* peak flow rate.

In a randomized, double-blind, crossover study, 30 men with at least a 6-month history of LUTS were randomized to receive tamsulosin versus tamsulosin plus 20 mg tadalafil daily for 45 days and then switched to the other treatment modality for a further 45 days (Bechara et al., 2008). The IPSS and IPSS QoL score did decrease with both treatments, but did with combination of the drugs (–9.2 vs. –6.7; –2.5 vs. –1.8; $P < 0.05$). Similar findings were reported in a trial investigating the efficacy of the combination of 20-mg tadalafil once daily and 10-mg alfuzosin (Liguori et al., 2009). A greater increase of PFR was found in patients who received combination therapy (+29.6%) compared with patients who received either alfuzosin monotherapy (+21.7%) or tadalafil monotherapy (+9.5%).

The effect of PDE5I therapy in addition to previous α_1-blocker therapy was investigated in a randomized trial that enrolled 60 men with persistent storage LUTS after 2 weeks of therapy with tamsulosin (Gacci et al., 2012b). Patients were randomized to receive tamsulosin plus placebo versus a combination of tamsulosin and 10 mg vardenafil once daily for 12 weeks. There was a between-group significant difference in PFR (placebo, +0.07 mL/s, vardenafil, +2.56 mL/s; $P = 0.03$); average urinary flow rate (placebo, –0.15 mL/s, vardenafil, +1.02 mL/s; $P = 0.03$), and IPSS storage subscore (placebo, –1.67, vardenafil, –3.11; $P = 0.03$). Vardenafil was well tolerated with no treatment discontinuation because of AEs.

In a comparable trial, the addition of 5 mg tadalafil once daily was investigated in patients with persisting LUTS despite therapy with silodosin for at least 1 month (Yoshida et al., 2017); the add-on therapy promoted a greater reduction in all symptom scores and a greater increase in PFR.

Gacci et al. (2012a) performed a meta-analysis of randomized trials comparing combination therapy with PDE5Is and α_1-blockers with α_1-blockers alone. Overall, a combination of the two drugs led to a mean reduction of the IPSS of 1.8 (95% CI, –3.7 to – 0.0) and a mean increase of PFR of 1.5 mL/s

(95% CI, 0.9 to 2.2 mL/s). The rates of AEs were 6.8% and 5.1% in the combination therapy group and the α_1-blocker alone group, respectively. The most commonly reported AEs were flushing, gastroesophageal reflux, headache, and dyspepsia.

Finally, the effect of a single fixed-dose compound combining either 0.2 or 0.4 mg tamsulosin with 5 mg tadalafil compared with tadalafil alone was investigated (Kim et al., 2017) in a double-blind, active-controlled trial for 12 weeks. The findings showed that the 0.4 mg tamsulosin/5 mg tadalafil combination was superior to tadalafil alone in terms of LUTS relief (IPSS change, –9.46 vs. –8.14; $P = 0.03$).

Although currently available data on combination therapy with PDE5Is and α_1-blockers are encouraging, further data concerning safety and cost-effectiveness of this treatment are needed to prove a clinical benefit in LUTS patients.

Given that both drugs are vasodilators, the FDA and the European Medicines Agency (EMA) do not recommend the combination of tadalafil with α_1-blockers because of a significant risk for hypotension. However, this risk is lower with uroselective α_1-blockers. As such, PDE5Is should be carefully administered to patients receiving α_1-blocker therapy. In patients who are stable with α_1-blocker therapy, PDE5I therapy should be initiated at the lowest recommended starting dose. Similarly, in those men already taking an optimized dose of PDE5Is, α_1-blockers therapy should be initiated at the lowest dose.

Phytotherapy

The use of plants and plant products for a therapeutic purpose, defined as phytotherapy, gained a significant role in the treatment of patients with BPH over the past two decades (Fourcade et al., 2008; Smith et al., 2015). The current role of phytotherapy in the management of BPH is discussed in the following sections.

Composition of Phytotherapy Extracts

Phytotherapeutic agents are composed of extracts derived from the roots, seeds, bark or fruits of plants (Table 145.19). Plant extracts contain a variety of chemical compounds, including phytosterols, plant oils, fatty acids, and phytoestrogens (Table 145.20). Several strategies have been reported regarding extraction from the source, with differences in terms of method, time, temperature, pressure, and solvents used; therefore, **the exact composition of each agent is unique, and there is a huge discrepancy in terms of quantitative and qualitative composition of the extracts obtained from the same plant.** This issue has a direct reflection on the beneficial effects of the compound.

TABLE 145.19

Origin of Plant Extracts

SPECIES	COMMON NAME
Serenoa repens, Sabal serrulata	Saw palmetto berry, American dwarf palm
Hypoxis rooperi	South African star grass
Pygeum africanum	African plum tree
Urtica dioica	Stinging nettle
Secale cereale	Rye pollen
Cucurbita pepo	Pumpkin seed
Opuntia	Cactus flower
Pinus	Pine flower
Picea	Spruce

TABLE 145.20

Components of Plant Extracts

Phytosterols	β-Sitosterol δ5-Sterol δ7-Sterol Stigmasterol Campesterol
Phytoestrogens	Coumestrol Genistein (isoflavone) Flavonoids Free fatty acids Esterified fatty acids
Terpenoids	Lectins Polysaccharides Aliphatic alcohols Plant oils

Although single plant preparations are available, many companies manufacture combination products (two or more plant extracts) in an attempt to provide enhanced efficacy, improve marketability, and provide a unique product that can be registered.

Mechanism of Action

The biologic activity of phytotherapeutic agents has been extensively assessed in both in vitro and animal studies; however, a full understanding of the mechanisms of action of these compounds is still lacking.

Two agents have been mainly investigated in preclinical studies: the extract of the American dwarf palm (saw palmetto, *Serenoa repens*) and the extract from the bark of the African plum tree *(Pygeum africanum)*. Several mechanisms of action have been proposed for these agents (Table 145.21); among them, the anti-inflammatory effect, 5α-reductase inhibition, and the apoptotic and antiproliferative effect caused by growth factor alteration have received the greatest attention (Buck 2004).

TABLE 145.21

Suggested Mechanisms of Actions of Plant Extracts[a]

Inhibition of 5α-reductase

Anti-inflammatory action
Interference with growth factors
Antiandrogenic effects
Estrogenic effects
Inhibition of aromatase
Decrease of sex hormone–binding globulin
Alteration of cholesterol metabolism
Action on α-adrenergic receptors
Free-radical scavenging
Alteration of lipid peroxidation
Modulation of prolactin-induced prostatic growth
Protection of bladder and detrusor function
Placebo effect

[a] The most investigated mechanisms are highlighted in bold.

The anti-inflammatory effect of plant extracts is caused by the inhibition of cyclooxygenases and lipoxygenases in the eicosanoid cascade. Prostaglandins and leukotrienes are generated via cyclooxygenases and lipoxygenases and play a key role in the inflammation response, which, in turn, is associated with BPH pathogenesis. Flavone, a phytoestrogen commonly found in plants and herbs, is a strong inhibitor of cyclooxygenase (Alcaraz and Ferrandiz 1987; Mower et al., 1984). In vitro studies showed that the lipidosterolic extract of *Serenoa repens* was able to inhibit the production of leukotrienes by neutrophils in human tissues (Paubert-Braquet et al., 1997). The acid lipophilic fraction of the compound was deemed responsible for this effect. Similarly, inhibition of phospholipase A_2 activity, along with a consequent reduction of prostaglandin synthesis, has also been observed with *Serenoa repens* in vitro (Plosker and Brogden, 1996).

The antiandrogenic action of *Serenoa repens* has been associated with the following (Buck, 2004):

- Inhibition of 5α-reductase isoenzymes I and II
- Inhibition of DHT binding to the cytosolic androgen receptor
- Inhibition of nuclear estrogen receptors in prostatic tissue

- Modulation of prolactin-induced prostatic growth by receptor signal transduction

The inhibition of 5α-reductases is associated with the presence of free fatty acids in the extract (Rhodes et al., 1993). However, this effect has been observed mainly in vitro and has not been confirmed in studies conducted on human prostatic samples (Weisser et al., 1996). Of note, in a large multicenter trial comparing *Serenoa repens* with finasteride, no effect on PSA levels was observed for *Serenoa repens*–treated patients, and only a 6% PV reduction was found (Carraro et al., 1996).

In a study evaluating the effect of *Serenoa repens* on castrated rats receiving estrogen and testosterone therapy, Paubert-Braquet et al. (1996) suggested an active role of the plant extract in reducing the increase in prostate weight associated with hormone treatment. Similar results were observed in a hyperprolactinaemic rat model (Van Coppenolle et al., 2000).

The apoptotic and antiproliferative effects of plant extract have been demonstrated in vitro. *Serenoa repens* decreased the proliferative index in BPH human prostate tissue (Vacherot et al., 2000). Moreover, in vitro studies with *Pygeum africanum* demonstrated an inhibitory effect on both basic fibroblast growth factor– and estrogen growth factor–induced human and rat prostate fibroblast proliferation (Paubert-Braquet et al., 1994; Yablonsky et al., 1997). Similarly, *Serenoa repens* has also showed inhibition of basic fibroblast growth factor– and estrogen growth factor–induced proliferation of human BPH prostate cells retrieved from biopsy specimens (Paubert-Braquet et al., 1998). Finally, in a study conducted on two different BPH cell lines, the lipidosterolic extract of *Serenoa repens* was able to alter the expression of genes involved in both proliferation and apoptosis (Sirab et al., 2013).

Despite the considerable amount of preclinical data, there is no certainty regarding the link between the biologic mechanisms observed in vitro and in animal studies and the clinical effects of phytotherapeutic agents.

Current Role of Phytotherapy in the Treatment of Patients With Lower Urinary Tract Symptoms

Wide population-based studies assessed the rate of prescriptions of phytotherapeutic agents in recent decades. For example, Fourcade et al. (2008) reported the management profile of patients medically treated for BPH in four

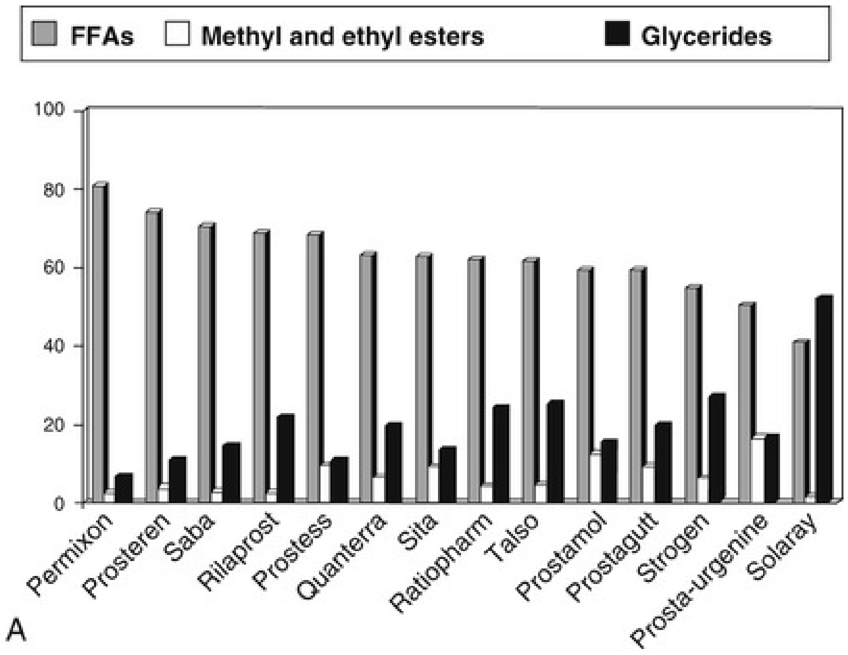
European countries. **Phytotherapy was the second most commonly prescribed therapy (23.5%), after α$_1$-blockers (62.5%).** The rate of prescriptions of phytotherapeutic agents differed among countries, reaching a rate of 49.6% in France. This is mainly caused by the differences in the commercialization policy of these products across countries. Patients who were prescribed phytotherapy showed an overall lower IPSS compared with those who were prescribed other drugs. Moreover, in a small percentage of cases (1.25% of overall prescriptions), phytotherapy was prescribed in combination with α$_1$-blockers. These data were further confirmed in a study involving a larger population of European patients evaluated from 2004 to 2008 (Cornu et al., 2010). The authors observed a huge variation in the rate of phytotherapy prescriptions for LUTS treatment, ranging from 0% to 40% of the overall BPH medical prescriptions across countries. Similarly, the use of phytotherapy in the United States has escalated; although the data may be outdated, it was estimated that more than $1 billion is spent per year in the United States alone for these products (Lowe and Fagelman, 1999).

International clinical guidelines do not include a specific recommendation regarding the use of phytotherapy in the treatment of patients with LUTS (McVary et al., 2011; Oelke et al., 2013)**. This is because the significant heterogeneity among commercialized products hampers the possibility to draw reliable conclusions on the efficacy of each different agent.**

Serenoa Repens (Saw Palmetto Berry)

The extract of the berry of the American dwarf palm (saw palmetto), *Serenoa repens* (also known as *Serenoa serrulata*), is the most popular and widely studied phytotherapeutic agent for the treatment of LUTS.

There is a wide heterogeneity across studies in terms of the methods of extraction and solvents used for herbal preparations. In a study comparing different marketed *Serenoa repens* extracts according to their free fatty acid content, Habib and Wyllie (2004) observed substantial heterogeneity among the products investigated (Fig. 145.19A). Similarly, Booker et al. (2014) analyzed 57 samples of *Serenoa repens* obtained from retail outlets in several countries and reported that the content of free fatty acids declared on the package differed by 9.9% to 460.4% from the actual amount measured. Given that free fatty acids are considered the main biologic active component of the herbal preparation, these results suggest a possible discrepancy in the efficacy between marketed compounds. Indeed, in a study assessing the biologic activity of different batches of seven different *Serenoa repens* extracts, Scaglione et al. (2008) observed a considerable variation in the inhibition of 5α-reductases among different extracts and batches of the same extract (Fig. 145.19B).



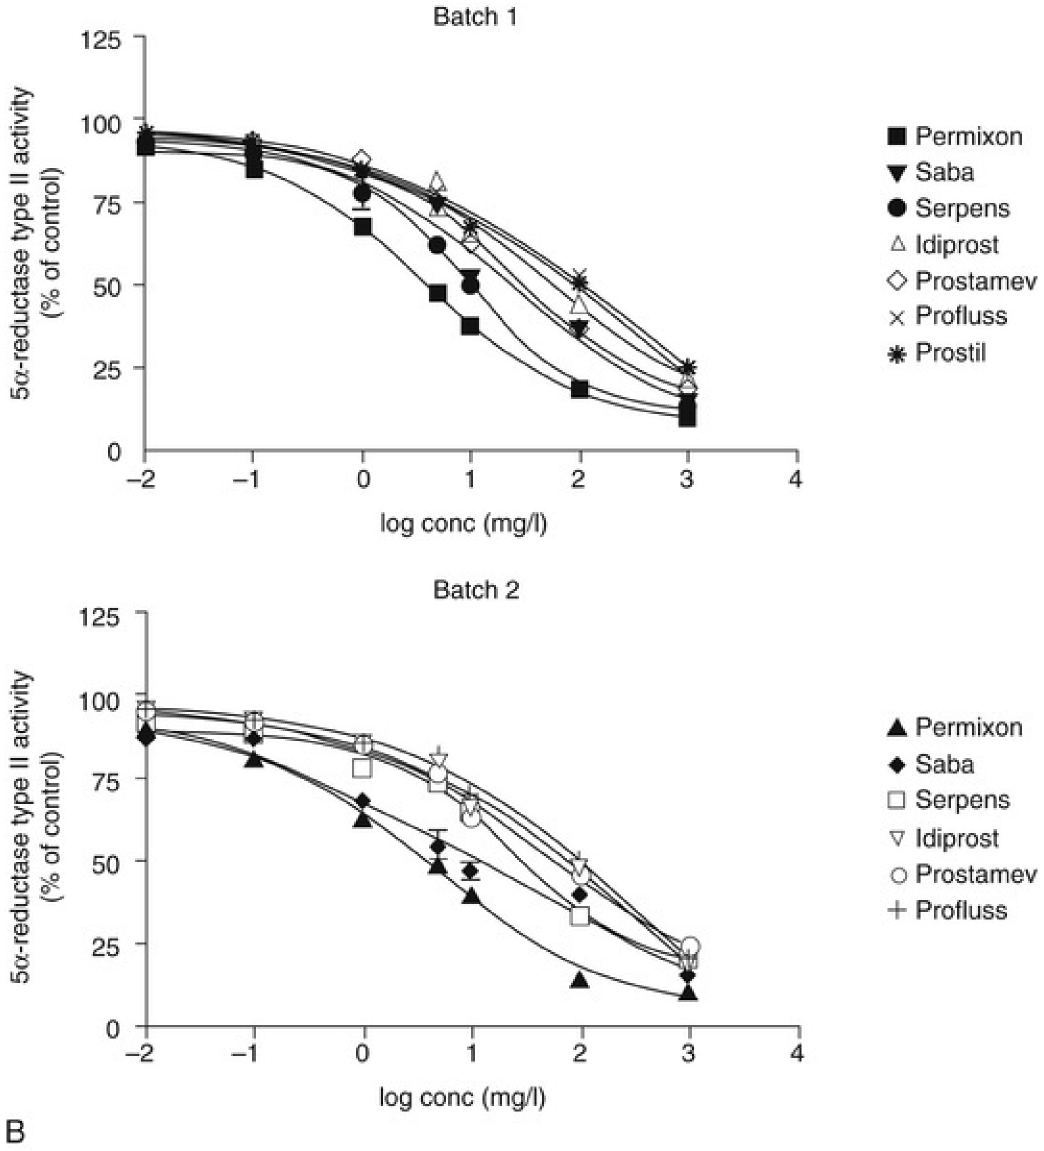


FIG. 145.19 (A) Visual representation of the content of 14 brands of *Serenoa repens* as determined by analysis. (B) Inhibition of 5α-reductase type 2. Enzyme activity is expressed as a percentage of the control (the conversion of 1 μM testosterone in the absence of inhibitors is defined as 100% activity). *FFAs,* Free fatty acids. (A, From Habib FK, Wyllie MG. Not all brands are created equal: a comparison of selected components of different brands of Serenoa repens extract. *Prostate Cancer Prostatic Dis* 7(3):195–200, 2004. Figure 2, p. 198. B, From Scaglione F, Lucini V, Pannacci M, et al. Comparison of the potency of different brands of Serenoa repens extract on 5alpha-reductase types I and II in prostatic co-cultured epithelial and fibroblast cells. *Pharmacology*82[4]:270–275, 2008. Figure 2, p. 273.)

Most of the trials assessing the clinical efficacy of *Serenoa repens* have been conducted with hexane, ethanolic, and supercritical CO_2 extracts (all commercially available in Europe), whereas in some studies the type of extract is not specified. The results of placebo-controlled RCTs on *Serenoa repens* are reported in Table 145.22.

IPSS, International Prostate Symptom Score; *NR,* not reported; *NS,* not significant.

In the first meta-analysis reporting data from 18 randomized trials comparing *Serenoa repens* with placebo ($N = 14$), finasteride ($N = 3$), or two different formulations of the drug ($N = 1$), a positive effect of *Serenoa repens* on LUTS relief was observed (Wilt et al., 1998). Therapy in the studies included lasted from 4 to 48 weeks. The authors found a significant change in mean symptom scores (–1.41 points), nocturia episodes (–0.76), and PFR (+1.93 mL/s) for patients treated with *Serenoa repens* compared with placebo. Moreover, *Serenoa repens* was not inferior to finasteride in terms of symptom score reduction and PFR increase. AEs were mild and infrequent and equally reported, even in the placebo group.

These results were not confirmed in the updated versions of the review (MacDonald et al., 2012; Tacklind et al., 2009, 2012); indeed, the trials included in the first meta-analysis by Wilt et al. (1998) were mostly underpowered, dealing with short-term treatment courses and used different outcomes and symptom scale scores. Tacklind et al. (2009) published an update including nine new trials involving a total of 2053 patients. *Serenoa repens* was not superior to placebo in terms of symptom score reduction, PFR increase, and PV reduction. Of note, in one trial assessing differences between *Serenoa repens* and finasteride (Carraro et al., 1996) and in two trials comparing *Serenoa repens* and tamsulosin, the plant extract was not inferior to the active control in terms of symptom score reduction and PFR increase (Debruyne et al., 2002; Hizli and Uygur 2007).

In the last review updates (MacDonald et al., 2012; Tacklind et al., 2012), two high-quality long-term trials were included (Barry et al., 2011; Bent et al., 2006). In the first trial, 225 men with moderate to severe symptoms were randomized to receive either 160 mg *Serenoa repens* twice daily (supercritical CO_2 extract) or placebo for 1 year (Bent et al., 2006). In the second multicenter trial, 369 men were randomized to receive a dose escalation of *Serenoa repens* up to 960 mg/day (ethanolic extract) or placebo for 72 weeks (Barry et al., 2011). Both trials used the validated AUASI (IPSS) to assess symptoms, and reported no difference between groups at the end of treatment. Likewise, PFR and PV modifications that occurred after active treatment were comparable to those that occurred with placebo.

Overall, these results suggest that *Serenoa repens* therapy does not relieve LUTS or increase PFR compared with placebo in men with BPH, even at double or triple the usual dose. However, it has been recognized that these results could have been affected by the heterogeneity of the extracts used in the different trials, therefore not being applicable to all marketed products.

In this context, the hexane extract of *Serenoa repens* (commercially known as Permixon) has been shown to have higher biologic activity along with the lowest variability from batch to batch in terms of free fatty acid content (Habib and Wyllie 2004; Scaglione et al., 2008), possibly suggesting a higher efficacy of this specific extract. Novara et al. (2016) reported the results of a meta-analysis including only RCTs assessing the efficacy of Permixon. Overall, seven trials compared Permixon with placebo, two trials compared Permixon plus tamsulosin with placebo and tamsulosin alone, and one trial compared Permixon with finasteride. The results of the meta-analysis showed that Permixon was more effective than placebo in reducing the number of nocturnal voids (–0.31) and increasing PFR (+3.37 mL/s). Moreover, Permixon was not inferior to tamsulosin monotherapy and short-term finasteride therapy in reducing IPSS and increasing PFR. Permixon's safety profile was favorable: there were no differences in reported AEs and rates of drug withdrawal compared with placebo.

Recently, the combination of silodosin and Permixon was investigated, showing higher rates of patients reporting clinically meaningful reduction of the IPSS as compared with silodosin monotherapy (Boeri et al., 2017).

In 2015, the EMA recognized the hexane extract of *Serenoa repens* (Permixon) as a well-established medicinal product according to the results of randomized trials showing a good efficacy and tolerability profile.

***Serenoa repens* has shown only mild gastrointestinal side effects reported, especially when taken on an empty stomach. It is advised to take *Serenoa repens* with food at the daily dose of 320 mg.** Few cases of suspected interactions with anticoagulants (warfarin) have been reported. As such, a warning has been included in the product monograph.

Conversely, the ethanolic and supercritical CO_2 extracts currently lack significant data to support their clinical efficacy.

Pygeum Africanum (African Plum)

The extract from the bark of the African plum tree, *Pygeum africanum*, has been used for the treatment of LUTS in Europe since 1969. The biologic activity of this plant extract is not completely clear yet; however, besides the previously discussed mechanisms, data from animal models have demonstrated a modulation of bladder contractility associated with the administration of *Pygeum africanum* (Levin et al., 1996).

In the first review of open-label and comparative studies assessing the effect and safety of *Pygeum africanum* to treat LUTS, an overall positive effect of the plant extract in terms of symptom relief and PFR increase was reported (Andro and Riffaud, 1995). However, the review included only results from uncontrolled studies, and a quantitative meta-analysis was not performed. Wilt et al. (2002b) conducted a subsequent meta-analysis including 18 randomized trials involving 1562 patients. Among the trials included, 11 compared *Pygeum africanum* with placebo, whereas other plant extracts were used as active control groups in the other trials. Most trials were short-term, with an 8-week mean length; the most commonly used formulation of *Pygeum africanum* was a standardized extract at a dose of 100 to 200 mg daily. Pooled analyses of five double-blind trials showed that men treated with *Pygeum africanum* were more than twice as likely to be rated by their physicians as having overall relief of symptoms compared with those who received placebo (65% vs. 30%; relative risk, 2.1). The lack of standardized tools to measure symptom relief was the main limitation of these findings. Likewise, the authors reported a significant increase in PFR of 23% in the *Pygeum africanum* group. In terms of safety, most of the reported AEs were mild in nature and comparable in terms of frequency with those in the placebo group.

Overall, *Pygeum africanum* has been shown to be more effective than placebo in treating men with LUTS, although the benefit appears modest

and is only reported at short-term follow-up.

Hypoxis Rooperi (South African Star Grass)

β-Sitosterol is a phytopharmacologic extract containing a mixture of phytosterols and is commonly derived from South African star grass, *Hypoxis rooperi*. The biologic activity of β-sitosterol has been related to an anti-inflammatory effect (inhibition of prostaglandin metabolism) (Lowe and Ku, 1996).

The two main preparations of β-sitosterol have been marketed with the names Harzol (containing 50% of a nonglucosidic β-sitosterol form) and Azuprostat (containing β-sitosterol from *Hypoxis rooperi* and from *Pinus* [pine] and *Picea* [spruce]). Both compounds have been evaluated in RCTs, with overall good efficacy being shown (Berges et al., 1995; Klippel et al., 1997).

Wilt et al. (1999) reported pooled analysis of four placebo-controlled studies assessing the safety and efficacy of β-sitosterols in men with LUTS. Two studies used Azuprostat, one study used Harzol, and one study used a preparation of 100% β-sitosterol (WA184). Overall, therapy courses ranged from 4 to 26 weeks. The pooled analysis showed relief of urinary symptoms (4.9-point reduction in IPSS) and increase of PFR (+3.91 mL/s) that were significantly greater than with placebo. The PVR volume reduction was 28.6 mL with β-sitosterol. AEs were mild and comparable in frequency to those observed with placebo.

Overall, this evidence suggests that preparations with β-sitosterols are effective in relieving symptoms and increasing flow rates at short-term assessment; however, the large reported effect, which is even greater than the effects observed with other proper pharmacologic compounds, raises concern regarding the reliability of these data.

Other Plant Extracts and Lycopene

Other plant extracts, including extracts of *Urtica dioica*, *Cucurbita pepo*, *Opuntia*, and *Secale cereale* (see Table 145.19), have been scantly and not homogeneously analyzed in a clinical setting.

Cernilton is a compound prepared from the pollen of rye *(Secale cereale)*, and its efficacy has been assessed in four randomized trials. Wilt et al. (2000) reported pooled analyses of data from these trials. Overall, two trials were placebo-controlled trials, and the other two used a different plant extract as an active control. The results showed that Cernilton was superior to placebo in terms of self-reported relief of overall symptoms (relative risk, 2.4) and nocturia (relative risk, 2.05). Conversely, there was no difference in terms of PFR and average flow changes from baseline between patients treated with Cernilton and those receiving placebo. All studies were short-term (maximum 24 weeks), and the overall quality was deemed to be poor.

In conclusion, although Cernilton seems to provide modest relief of symptoms, its efficacy in treating patients with LUTS remains questionable.

Besides plant extracts, there is a considerable amount of data assessing the effect of dietary antioxidants on prostatic diseases; among them, lycopene and selenium have shown controversial results in terms of LUTS relief (Holton et al., 2016; Kristal et al., 2008).

Lycopene is a nonprovitamin A carotenoid with potent antioxidant and anti-inflammatory activity that has been found to modulate cell growth in the prostate through inhibition of 5α-reductase and IL-6 signaling (Holzapfel et al., 2013). Similarly, selenium exerts epigenetic and antioxidant effects that may play a role in prostate growth and inflammation (Vinceti et al., 2014). A combination of lycopene and selenium with *Serenoa repens* (Ser-Ly-Se; commercially known as Profluss) has been proposed with the aim to improve the efficacy of the latter in the treatment of patients with LUTS. Preclinical data showed that Ser-Ly-Se was more effective than *Serenoa repens* alone in decreasing the prostate inflammatory response, decreasing growth factor expression, and improving histologic features (Bonvissuto et al., 2011). Similarly, in a rat model treated with testosterone, the administration of Ser-Ly-Se inhibited prostate growth by 83% (Altavilla et al., 2011).

In a randomized, double-blind, multicenter study, 225 patients were treated with either Ser-Ly-Se, tamsulosin, or a combination of both drugs (Morgia et al., 2014). The results showed that the combination of tamsulosin plus Ser-Ly-Se was superior to each drug alone in terms of symptom relief and PFR increase after 12 months of treatment, thus suggesting a possible role of combining an α_1-blocker with a plant extract administered together with two potent antioxidants for the treatment of patients with moderate LUTS.

Summary

The use of phytotherapy for the treatment of LUTS has greatly increased worldwide over the past two decades; however, randomized clinical trials have reported inconclusive results on the efficacy of phytotherapeutic

agents in terms of symptom relief and uroflow parameter improvement. Large and long-term trials did not report any difference between phytotherapy and placebo.

There is a huge variability in the biologic activity of each marketed compound as a consequence of the lack of a standard extraction method, thus making comparison difficult between data. For these reasons, both European and American guidelines do not provide specific recommendations for the use of phytotherapy in treating patients with LUTS related to BPH.

***Serenoa repens* is the most widely investigated phytotherapeutic agent for the treatment of LUTS and is recommended at a daily dose of 320 mg taken with food.**

Prognosis of Patients Receiving Medical Treatment for Lower Urinary Tract Symptoms

Longitudinal population-based studies provided data showing that BPH is a progressive disease (Roehrborn, 2008). The Olmsted study, including 2115 men 40 to 79 years of age followed up for 12 years, showed an average IPSS increase of 0.18 points per year, a decrease in PFR of 2% per year, and a prostate growth rate of 1.9% per year (Fitzpatrick, 2006). As a progressive disease, BPH may lead to serious events other than symptom deterioration, including AUR, hypoactive detrusor activity, and eventually hydronephrosis.

Medical therapy has been demonstrated to reduce the risk for BPH progression and to avoid the need for BPH surgery. In this context, long-term RCTs allowed the identification of patients at higher risk for progression who may gain greater benefit from treatment.

In the MTOPS study, the cumulative incidence of disease progression in the placebo group (identified as symptom deterioration in most cases) was 17% over a 4-year period (McConnell et al., 2003). Patients receiving treatment with a single agent (either doxazosin or finasteride) showed a risk reduction in BPH progression of 34% to 39%, further increasing to 66% for those treated with a double agent; of note, the risk for AUR and BPH-related surgery was significantly reduced only by finasteride treatment. Similar findings were observed in the CombAT trial (Roehrborn et al., 2008a) and in the ALTESS (Roehrborn, 2006). According to the results of these trials, baseline characteristics associated with a higher risk for BPH clinical progression were higher PSA values, larger prostates, and greater PVR volumes; these factors should be carefully considered when patients are being counseled for LUTS treatment.

Recent post hoc analyses from another large prospective trial including patients treated with either dutasteride or placebo (REDUCE trial) provided further evidence on the risk for BPH progression (Simon et al., 2016). The REDUCE trial included more than 3000 men with mild to no symptoms at the baseline (IPSS <8); Simon et al. (2016) looked at the risk for developing LUTS (defined as IPSS >14) in a subgroup of mild-asymptomatic patients treated with placebo. They showed that those with a prostate size of 40 to 80 mL had a higher risk for further developing LUTS (HR, 1.67) as compared with those with a PV of 40 mL or lower. Similarly, a lower PFR at baseline was associated with a higher risk for developing LUTS in the same subgroup of patients. Data from the CONDUCT study, assessing the efficacy of a fixed-dose combination of dutasteride and tamsulosin as compared with a WW approach, suggested that the degree of bother associated with LUTS at the baseline (BII) could be a better indicator of whether or not a patient will benefit from medical treatment (Rosa et al., 2016). Indeed, the superiority of combination therapy over WW in terms of IPSS reduction at 2 years was observed only in patients with higher BII scores at baseline.

The dynamic changes of baseline variables are also considered as a predictor of disease progression: symptom worsening and PVR volume changes over time have been associated with a higher risk for AUR in long-term RCTs (Roehrborn, 2008). For instance, in the placebo arms of the MTOPS trial, patients who did not develop AUR showed a stable PVR volume throughout the period investigated.

Medical treatment of LUTS should be tailored to the patient's baseline characteristics, and the effect of therapy should be properly monitored over time. International clinical guidelines suggest properly following up patients receiving medical treatment for LUTS/BPH: patients treated with either α_1-blockers or 5ARIs should be assessed after 4 to 12 weeks to check the initial response to therapy (for α_1-blockers) and the occurrence of AEs. Patients should be reassessed after 6 months and annually thereafter to monitor changes in symptoms, uroflowmetry parameters, and PVR volume. Moreover, serum PSA level should be carefully monitored in patients treated with 5ARIs with a life expectancy greater than 10 years (Oelke et al., 2013).

Key Points

- α_1-Blockers are the first-line treatment for patients with moderate to severe LUTS.
- The uroselective α_1-blockers tamsulosin, silodosin, and alfuzosin showed the best tolerability profile.
- 5ARIs are effective in reducing the risk for disease progression and the need

for invasive treatment.

- Patients with predominant storage symptoms may benefit from combination therapy with antimuscarinic drugs.
- PDE5Is are effective in relieving LUTS, either alone or in combination with α_1-blockers.
- There is no consensus on the efficacy of phytotherapy for LUTS treatment, although encouraging results have been published for the hexane extract of *Serenoa repens* and for the combination of *Serenoa repens* with lycopene and selenium.

Acute Urinary Retention

AUR is defined as a sudden and painful inability to void voluntarily (Emberton and Anson, 1999)**; it is a severe complication of BPH and is a major public health issue.** Two distinct forms of AUR can be distinguished in clinical practice: *spontaneous AUR*, as a consequence of the natural history of progressive BPH, and *precipitated AUR*, developing after a precipitating event other than BPH, such as surgical procedures with general or locoregional anaesthesia, UTIs, bladder overdistension, or medications with anticholinergic or sympathomimetic agents (McNeil, 2006).

Data from longitudinal population studies provided information on the incidence and risk factors associated with spontaneous AUR (Oelke et al., 2015). Older age, severe LUTS, low PFR, high PVR volume, large PV, and high serum PSA level are all recognized predictors of AUR (Jacobsen et al., 1997). The overall incidence of AUR in the general male population has been reported to be between 2.2 and 8.5 events per 1000 person-years (Table 145.23). In a large population study including 165,527 adult men from the United Kingdom, the incidence of AUR was reported to be as high as 3.1 per 1000 person-years, with about 65% of cases being spontaneous AUR (Cathcart et al., 2006). In the Olmsted County study, including a large US male population 50 years of age or older, up to 8.5 events per 1000 person-years were reported (Roberts et al., 2005).

TABLE 145.23

Incidence of AUR in the General Population and Among Men With LUTS

STUDY	COUNTRY	POPULATION	INCIDENCE	
			GENERAL POPULATION (RATE PER 1000 PERSON-YEARS [95% CI])	MEN WITH LUTS (RATE PER 1000 PERSON-YEARS [95% CI])
Verhamme et al., 2005	Netherlands	56,958 men ≥45 years of age with no history of	2.2 (2.0–2.4)	35.9 (30.5–42.0)

		AUR		
Cathcart et al., 2006	United Kingdom	165,527 men	3.1	NR
Meigs et al., 1999	United States	6100 men 45–83 years of age without prostatectomy for BPH or AUR	4.5 (3.1–6.2)	NR
Roberts et al., 2005	United States	2115 men 40–79 years of age	8.5[a] (6.4–11.2)	18.3[b] (11.3–28.0)

[a] *N,* 1193; men 50 years of age or older.

[b] *N,* 238: selected cohort of men with characteristics meeting selection criteria for the Medical Therapy of Prostatic Symptoms study.

AUR, Acute urinary retention; *BPH,* benign prostatic hyperplasia; *CI,* confidence interval; *LUTS,* lower urinary tract symptoms.

Modified from Oelke M, Speakman MJ, Desgrandchamps F, Mamoulakis C. Acute urinary retention rates in the general male population and in adult men with lower urinary tract symptoms participating in pharmacotherapy trials: a literature review. *Urology* 86(4):654–665, 2015.

The incidence of AUR is even higher in populations of patients complaining of LUTS. In a retrospective Dutch study, 35.9 episodes of AUR per 1000 person-years among patients with LUTS were reported (Verhamme et al., 2005) (Fig. 145.20). Similarly, in a subcohort of the Olmsted County study including men with symptomatic BPH, the incidence of AUR was up to 18.3 per 1000 person-years (Roberts et al., 2005). Recently, in a Californian study investigating the temporal trend in the rate of patients presenting to the emergency department for AUR associated with BPH, Groves et al. (2013) reported an increase in the incidence of AUR from 4 per 1000 visits in 2007 to 5.23 per 1000 visits in 2010. These findings may be the consequence of either an increasing number of older men with advanced BPH or a larger proportion of patients receiving inappropriate treatment for LUTS in the primary care setting.

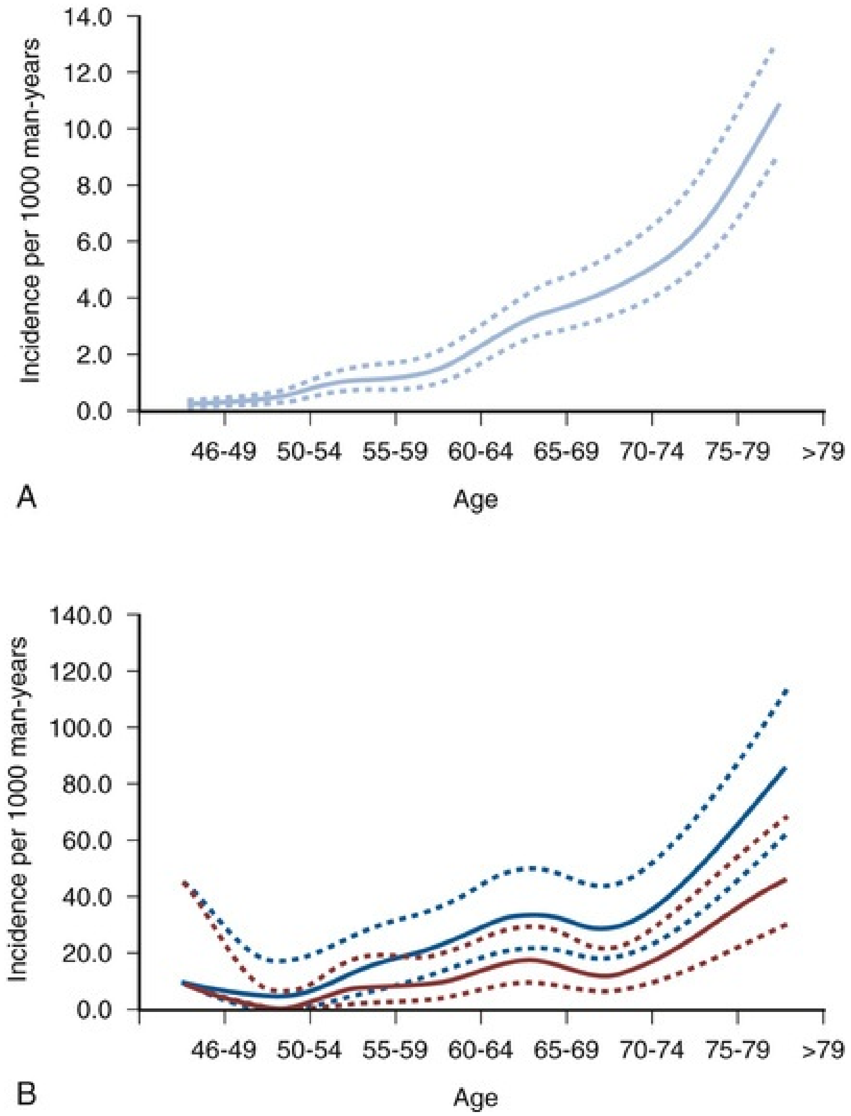

FIG. 145.20 Incidence of acute urinary retention in the general population of Dutch men (A) and in the population with lower urinary tract symptoms and benign prostatic hyperplasia (B). (From Verhamme KM, Dieleman JP, van Wijk MA, et al. Low incidence of acute urinary retention in the general male population: the triumph project. *Eur Urol* 47[4]:494–498, 2005.)

Management of Acute Urinary Retention

The initial management of AUR consists of immediate bladder decompression by catheterization. After catheterization, patients could undergo either immediate surgery or a TWOC. The advantage of immediate surgery relies on the early resolution of BOO, enabling spontaneous voiding and protecting both the bladder and the upper urinary tract from injury. However, emergency surgery has been associated with increased morbidity, thus shifting the paradigm of treatment toward a more conservative strategy (Fitzpatrick et al., 2012; Manikandan et al., 2004). The TWOC is based on the removal of the catheter after a few days from its placement, which allows the patient to return to normal voiding in about 60% of cases (Fitzpatrick et al., 2012; McNeil, 2006). There is substantial heterogeneity in the type and duration of catheterization and in the use of concurrent medical therapies. In a multi-institution study collecting data from 6074 patients treated worldwide for a first episode of AUR in the 2004 to 2008 period, TWOC was the treatment of choice in 78% of cases (Fitzpatrick et al., 2012). The duration of catheterization ranged from 3 to 8 days (median 5 days), and the success rate of TWOC was 61%. Moreover, among patients in whom TWOC failed, 43.5% underwent a second attempt, which was successful in 29.5% of cases, whereas a third attempt had a success rate of 26.4%. These data suggest that up to three TWOCs may be attempted before patients are counseled for more invasive treatments. **However, a high rate of patients with a successful TWOC will experience a subsequent AUR episode, with 80% of them failing to void within 6 months** (Cathcart et al., 2006). At this point, pressure-flow studies and surgery are indicated.

Advanced age, severe LUTS, and large volume drained at catheterization (≥1 L) are all factors associated with a higher risk for TWOC failure; similarly, failure is more likely in a patient with an episode of spontaneous AUR than in a patient experiencing AUR secondary to trigger events (Fitzpatrick et al., 2012; Yoon et al., 2015).

In a recent systematic review assessing the outcomes of TWOC, Yoon et al. (2015) underlined the substantial heterogeneity in terms of the duration of catheterization applied in clinical practice, with no study providing convincing data supporting a higher probability of success associated with either a short or a long catheterization time. In a small trial, the effect of clean intermittent self-catheterization was compared with a conventional TWOC after indwelling catheterization, showing higher success rates for patients undergoing intermittent catheterization (56% vs. 25%); however, this trial was not randomized, and patients managed with self-catheterization were younger and had a smaller prostate (Ko et al., 2012).

The dynamic component of obstruction, characterized by an increase sympathetic tone inducing the contraction of the smooth muscle fibers of the bladder neck, has been deemed to be partially responsible for urinary retention. For this reason, α_1-blockers have been widely used to increase the probability of a successful TWOC (Emberton et al 2008). In the Alfuzosin in Acute Urinary Retention study, patients who underwent emergency catheterization were blindly randomized to receive 10 mg alfuzosin once daily or placebo for 3 days; the results showed that α_1-blockers treatment was associated with a significantly higher success rate compared with placebo treatment (61.9% vs. 47.9%; $P = 0.01$) (McNeill et al., 2005). In a meta-analysis of eight RCTs assessing the benefit of using α_1-blockers before TWOC, Fisher et al. (2014) confirmed that the rate of successful TWOC was significantly higher with α_1-blockers compared with placebo (relative risk, 1.55; 95% CI, 1.36 to 1.76). Likewise, AUR recurrence was lower among patients treated with α_1-blockers. The duration of α_1-blockers therapy ranged from 1 to 3 days in seven of eight trials; the optimal duration of treatment has not been investigated yet.

Medical Therapy in the Prevention of Acute Urinary Retention

Long-term randomized trials of α_1-blockers and 5ARIs provided data on the effect of medical therapy for the prevention of AUR in patients with BPH.

Among α_1-blockers, data are available for alfuzosin, doxazosin, and tamsulosin therapy. In a post hoc analysis of the 2-year ALTESS, randomizing patients to receive 10 mg alfuzosin daily or placebo, the authors looked at the overall clinical progression of BPH defined as the occurrence of AUR, surgery, or symptom deterioration (Roehrborn, 2006). The **results showed that alfuzosin was not able to reduce the risk for AUR as compared with placebo (2.1% vs. 1.8%; $P = 0.8$).**

In the 4-year MTOPS trial, randomizing patients to receive doxazosin, finasteride, a combination of doxazosin and finasteride, or placebo, the cumulative incidence of AUR was compared among groups (McConnell et al., 2003); **AUR incidence did not differ between the placebo group (0.6 per 100 person-years) and the doxazosin group (0.4 per 100 person-years; $P = 0.2$), although patients treated with α_1-blockers showed an increased time to event compared with the placebo group.**

In the CombAT study, tamsulosin intake was associated with a 4-year AUR incidence of 6.8% (95% CI, 5.5% to 8%) (Roehrborn et al., 2010); the lack of a placebo arm did not allow a conclusion to be drawn regarding the benefit of tamsulosin in preventing AUR. **However, patients receiving both tamsulosin and dutasteride showed a risk reduction for AUR of 67.6% and 18.3% compared with tamsulosin and dutasteride alone, respectively, suggesting that treatment with 5ARIs plays a major role in preventing AUR over time.**

Key Points

- AUR is a common complication of BPH progression.
- A TWOC is the preferred management after initial decompression by bladder catheterization.
- The use of α_1-blockers is recommended to increase the odds of a successful TWOC.
- Dutasteride and finasteride have been shown to significantly decrease the risk for AUR in patients with moderate to severe LUTS.

Future Directions in Medical Treatment of Benign Prostatic Hyperplasia

Despite the efficacy of currently available treatments for LUTS, there are still a nonnegligible number of patients who do not benefit from medical therapy, thus deserving surgery. Surgical treatment is still considered the most effective and long-lasting treatment modality for BPH (McVary et al., 2011; Oelke et al., 2013).

Improvements in the knowledge of lower urinary tract physiology may lead to the development of new drugs aimed at further improving the effectiveness of medical treatment of LUTS/BPH. The active role played by the bladder urothelium and the interstitial cells in the physiopathology of LUTS is currently under investigation. Likewise, the transient receptor potential (TRP) channel family, cannabinoid receptors, purinergic receptors, and vitamin D_3 receptors have been considered as potential targets of newly developed drugs for LUTS management (Soler et al., 2013) (Fig. 145.21).

FIG. 145.21 Pathophysiologic mechanisms and targets for future nonsurgical therapy. (From Soler R, Andersson KE, Chancellor MB, et al. Future direction in pharmacotherapy for non-neurogenic male lower urinary tract symptoms. *Eur Urol* 64[4]:610–621, 2013.)

The effect of the vitamin D_3 receptor agonist elocalcitol has been investigated in vitro (Adorini et al., 2007; Morelli et al., 2007), with decreases in stromal prostate cell proliferation and interference with the androgen receptor signaling being observed. However, in a phase II RCT, treatment with elocalcitol failed to show an advantage over placebo in terms of PFR increase and symptom relief (Colli et al., 2006). Nonetheless, this drug remains currently under investigation (Digesu et al., 2012).

In an animal model, an orally active antagonist of the TRPV1 receptor, which belongs to the vanilloid TRP subfamily, was found to counteract bladder hyperactivity induced by cystitis (Charrua et al., 2009). Similarly, rats treated with a selective antagonist of TRPV4 showed a decreased voiding frequency and an increased voided volume (Everaerts et al., 2010). However, the effects of these compounds have not yet been investigated in humans.

The use of cannabinoids for the treatment of LUTS has been investigated in the setting of patients with multiple sclerosis. In a multicenter trial that enrolled 630 patients, the oral administration of a cannabis extract led to a significant reduction of incontinence episodes of 38% compared with 18% in the placebo group (Freeman et al., 2006).

Endothelin 1 was shown to be overexpressed in detrusor muscle of obstructed rabbits and to be responsible for detrusor contraction. The oral antagonist of endothelin-converting enzyme, which is responsible for endothelin 1 production, showed promising results in terms of inhibition of nonvoiding contractions in a hyperactive bladder animal model (Schröder et al., 2004).

Anti-inflammatory drugs have been also investigated as potential therapies for LUTS. Flavocoxid, a dual inhibitor of cyclooxygenase 2 and 5-lipoxygenase, reduced PV in a rat model via the enhancement of the proapoptotic proteins Bax and caspase 9 (Altavilla et al., 2012). Similarly, the combination of rofecoxib and finasteride led to a greater reduction in IPSS and greater PFR increase as compared with finasteride alone in a clinical setting (Di Silverio et al., 2005).

Other compounds, including Rho kinase inhibitors and purinergic receptor blockers, have shown promising results in preclinical studies, thus deserving further investigation (Füllhase et al., 2014). Finally, the effect of intraprostatic drug injection therapy to treat BPH has been investigated. In this context, NX-1207 is a new therapeutic protein with proapoptotic properties that has been tested in a phase II trial and showed a significant reduction of gland volume (Soler et al., 2013). Similarly, PRX302 is a PSA-activated channel-forming toxin that is able to decrease PV. The drug was tested in 33 patients with BPH, showing promising results in terms of IPSS reduction (Williams et al., 2007). Lastly, onabotulinumtoxinA, a form of botulinum neurotoxin, has been tested as an intraprostatic injected agent in a placebo-controlled trial, showing a significant reduction of IPSS and increase of PFR, along with a significant PV reduction (Marberger et al., 2013). All of these drugs deserve further clinical investigations before any implementation in the treatment algorithm for patients with LUTS.

Minimally Invasive and Endoscopic Management of Benign Prostatic Hyperplasia

Sevann Helo MD, R. Charles Welliver Jr, MD, Kevin T. McVary MD, FACS

Introduction

Urinary obstruction because of benign prostatic disease has probably been recognized to some degree since the earliest days of medicine. One of the earliest descriptions of benign prostatic hyperplasia (BPH) was described by Morgagni in the eighteenth century (Morgagni, 1760). Early treatments for BPH centered on open procedures utilizing both suprapubic and perineal approaches. These surgeries were prone to profound hemorrhage and led to unacceptable mortality and morbidity. The arrival of transurethral resection of the prostate (TURP) offered another option between watchful waiting and open prostatectomy (OP). However, with the rudimentary equipment at that time and an incomplete understanding of the postoperative physiology, this procedure continued to have an elevated morbidity and even mortality.

With the introduction of medical management in the 1990s, we began to see a decrease in the need for surgery to treat lower urinary tract symptoms related to BPH (LUTS/BPH). Medical management provided a lower-risk treatment option for patients over the previously unchallenged surgical treatments yet at a cost of lower benefit in urologic outcomes and the need for ongoing and often indefinite therapy. However, despite the strides made in optimizing medical management, many patients still need or request additional treatment in the form of surgical procedures.

The ever-expanding endoscopic options for LUTS/BPH include many minimally invasive surgical treatments (MISTs), allowing the practitioner to further parse the continuum between surgical approaches and medical management. Subsequently, the urologist witnessed an explosion in procedures available for the treatment of LUTS/BPH. These new technologies are often embraced with excitement; however, many do not live up to these initial expectations that were often based on small series of patients followed for a short duration.

As the pressure to accept a new technology grows with increasing marketplace competition, the urologist must be careful to embrace each new technology until the results have been thoroughly vetted. Often when new technologies or techniques are compared with the classic, monopolar TURP, outdated data are quoted that do not reflect contemporary TURP results. Additionally, there is a considerable placebo effect inherent to all LUTS/BPH treatments, and in nonrigorous study design such as an uncontrolled single series cohort, any inherent placebo or sham effect will be credited to the new technology.

In this chapter, we discuss the many endoscopic treatment options available to the patient and urologist for the treatment of LUTS/BPH. Special attention will be paid to inimitable advantages or disadvantages of these techniques/technologies with differences in patient outcomes highlighted. TURP held a unique position as the only endoscopic treatment for many decades, and the depth and variety of literature surrounding the procedure are impressive. This treatment is still clearly considered the gold standard, and almost any new technology inherently ends up compared with TURP in a randomized controlled trial (RCT) setting or by historical data.

Epidemiology and Marketshare

Marketshare

The rate of surgical treatment of LUTS/BPH has steadily decreased with the advent of medical therapy in the 1980s, only to be accelerated by the publication of the Veterans Affairs Cooperative Study and Medical Therapy of Prostatic Symptoms study (Bautista et al., 2003, Lepor et al., 1996). Analysis of hospital claims data of Medicare beneficiaries demonstrates a peak in the number of TURP procedures in 1987 (Lu-Yao et al., 1994; Wasson et al., 2000), with a 5% decrease per year seen between 1999 and 2005. Despite this decrease between 1999 and 2005, there was a 44% overall increase in surgical treatment of LUTS/BPH (all treatment options) mostly brought on by a **529% increase in thermotherapy or LASER treatment** (Yu et al., 2008).

The most recent installment of this series (Malaeb et al., 2012) showed an overall peak in surgical treatment for LUTS/BPH in 2005, with a subsequent 19.8% decrease until the end of the study in 2008. Throughout the entire study period, TURP continued to decrease, even with the introduction of the bipolar resection system. Thermotherapy and LASER therapy also had an overall decrease between 2005 and 2008, although LASER vaporization was the only treatment option to experience an increase since 2005. Review of case logs of surgeons undergoing certification or recertification reveals an increase in the number of LASER procedures from 11% to 44% between 2004 and 2010. The differential between LASER procedures and standard TURP was fairly equal from 2008 to 2010 (44% to 46% to 54% to 56%, respectively), as there was an increase in the number and proportion of urologists performing LASER procedures (Lowrance et al., 2013).

Another study utilizing the New York Statewide Planning and Research Cooperation System database showed a similar trend with LASER usage, which increased from 6.4% to 44.5% between 2000 and 2011, and TURP usage decreased from 72.2% to 48.3% (Chughtai et al., 2015). Additionally, the authors noted that Medicaid patients were less likely to undergo LASER surgery than those with private insurance (odds ratio [OR] 0.58), and that mid- to high-volume institutions were more likely to use LASER treatment than low-volume centers (OR 2.26). The socioeconomic factors affecting LASER usage and adoption are further illustrated by an analysis of payer data in Florida looking at both inpatient and ambulatory surgery discharges for LASER prostatectomy or TURP. Socioeconomic areas were characterized by lowest, medium, and highest terciles after being identified by zip code. A better socioeconomic environment correlated with offering LASER prostatectomy and with a more rapid adoption of the technique (Schroeck et al., 2013).

Epidemiology of Surgical Treatment for Benign Prostatic Hyperplasia

The prevalence of both LUTS/BPH and histologic BPH increases with age. **The Baltimore Longitudinal Study examined 1057 men and found that “prostatism” or BPH voiding dysfunction increased progressively from 26% in the fifth decade of life to 79% in the eighth decade of life** (Guess et al., 1990)**. Prevalence of symptoms related to an enlarged prostate increased from 26% of men 40 to 49 years of age to 46% of men older than 70 years of age in the Olmstead County Study** (Chute et al., 1993).

The prevalence of the histologic evidence of BPH follows a similar correlation with age. In the study from Berry et al. (1984), men in their eighth decade (82%) were more likely to have histologic evidence than men in their fourth decade (8%). The autopsy study by Robson (1964) found a prevalence of histologically confirmed BPH in prostates with gross enlargement of 14%, 37%, and 39% of men 50 to 59, 60 to 69, and older than 70 years of age, respectively.

Increasing Age

The risk for surgery related to BPH was noted to be considerably greater for an 80-year-old man than for a 40-year-old man in the Veterans Administration Normative Aging Study, which was carried out prospectively from 1961 to 1982 (Glynn et al., 1985). The retrospective New Haven Hospital Study (Lytton et al., 1968) also found an increasing incidence of surgery for BPH increasing through the eighth decade. Although intuitively, the advent of medical therapy may delay the need for surgical intervention of LUTS/BPH, a review of medical and surgical therapy in France between 2004 and 2008 revealed a slight decrease in mean age of patients treated for LUTS/BPH with medical or surgical therapy (Lukacs et al., 2013). The mean age of patients who received medical treatment decreased from 69.7 to 68.04 years and was associated with a 24% increase in use of medical therapy. Although the mean age of patients who underwent surgical treatment also decreased, from 71.5 to 69.0 years, the total number of surgical procedures decreased by 10% during the same period.

Effects of Medications for Benign Prostatic Hyperplasia

The successes of medical therapy for LUTS/BPH have led to the previously decreased rates of surgical management of BPH. **Subsequently, patients are now older at the time of surgical intervention than they were in previous years** (Vela-Navarrete et al., 2005) **and frequently have an increase in medical comorbidities** (Choi et al., 2012).

An interesting retrospective review of a single Canadian institution further highlighted changes in patients undergoing intervention for LUTS/BPH (Izard and Nickel, 2011). Patients who underwent TURP in 1988, 1998, and 2008 were compared with regard to preoperative use of BPH medications, indications for surgery, postoperative complications, and preoperative BPH-related events. Although TURP decreased by 60% between 1988 and 1998, an increase was noted in the percentage of total clinic patients undergoing TURP between 1998 and 2008. The indication for surgery of “failure of medical management” increased from essentially zero in 1988 to 36% in 1998 and to 87% in 2008. **Troublingly, adverse preoperative BPH-related events like acute urinary retention and hydronephrosis were more common in 2008 than in 1988. Additionally, postoperative complications and patients discharged with a catheter were more common in 2008 than in 1988**. This highlights the change in the type of patient who undergoes surgery and that medical therapy may be leading to a decompensated bladder and urinary tract. This is consistent with the findings of Flanigan et al. (1998), who found that patients who underwent immediate TURP had a more significant improvement in peak flow rates and symptom scores than men who underwent an extended period of watchful waiting. It appears that there is a consequence to the delay in effective treatment for many men. However, baseline characteristics of men who have significant deterioration in voiding without treatment have not been defined.

Prostate Size

Despite on overall lack of correlation between prostate size and bladder outlet obstruction (BOO), a correlation does seem to exist between prostate volume and the decision for surgical intervention. Although the data come from a period before medical treatment, Berry et al. (1984) did find a correlation between prostate size and the decision for surgical intervention. More contemporary data on the correlation between prostate size and need for surgery is sure to be skewed by multiple factors. The now common use of 5α-reductase inhibitors (5ARIs) will decrease both prostate size and the risk for surgery (McConnell et al., 1998; Roehrborn et al., 2002), suggesting that smaller glands are less likely to need treatment.

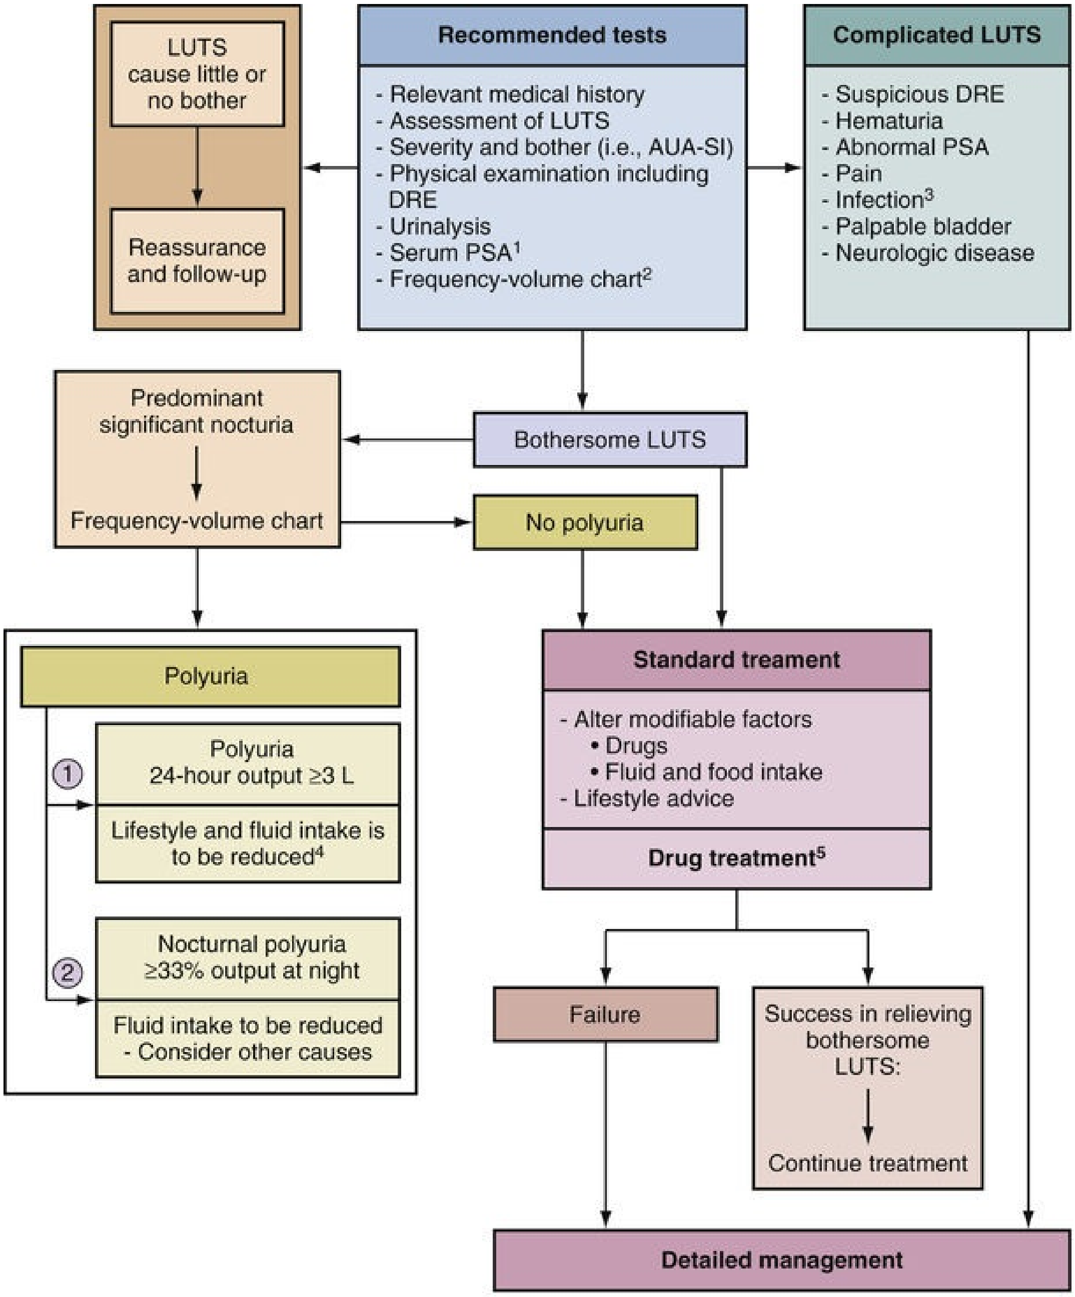
However, drawing any further conclusion about increased prostate size leading to surgery may have been contaminated because of the use of the other class of BPH treatments. Although not altering prostate gland size, α-blockers allowed for the relief of symptoms while their overall prostate growth continued unchecked. Patients who failed medical therapy and proceeded to surgery would thus have larger glands. This fact contaminates the concept that larger glands would lead to more surgical intervention as the common use of these medications "induced" a selection bias.

Key Points

- The incorporation of medical management and new technologies has changed which treatment options are selected for the treatment of LUTS/BPH.
- **LASER-based treatments are increasingly used, although multiple factors have affected acceptance.**
- Multiple factors have changed the usual patient that advances to surgical management of BPH in the preceding decades. Increasingly these are more challenging clinical scenarios.

Workup

The evaluation of LUTS/BPH should always include a detailed medical history and focused physical examination, which should include a brief neurologic screen, abdominal examination, and genitourinary examination including digital rectal examination (DRE). Urinalysis is another recommended test to screen for hematuria and urinary tract infection (UTI). According to American Urologic Association BPH guidelines, men with a predominant symptom of nocturia should complete a frequency-volume chart (voiding diary) to evaluate for nocturnal polyuria (American Urological Association, 2011; McVary et al., 2011). An algorithm for the basic and more detailed workup can be seen in Figs. 146.1 and 146.2. The specific goals for the patient should be clearly defined from both the standpoint of the patient and the treating physician. If the symptoms are not significantly bothersome or if the patient does not want treatment, no further evaluation is recommended.



LUTS cause little or no bother
Reassurance and follow-up
Recommended tests
- Relevant medical history
- Assessment of LUTS
- Severity and bother (i.e., AUA-SI)
- Physical examination including DRE
- Urinalysis
- Serum PSA1
- Frequency-volume chart2
Complicated LUTS
- Suspicious DRE
- Hematuria
- Abnormal PSA
- Pain
- Infection3
- Palpable bladder
- Neurologic disease
Predominant significant nocturia
Frequency-volume chart
Bothersome LUTS
No polyuria
Polyuria
①
Polyuria 24-hour output ≥3 L
Lifestyle and fluid intake is to be reduced4
②
Nocturnal polyuria ≥33% output at night
Fluid intake to be reduced - Consider other causes
Standard treament
- Alter modifiable factors
• Drugs
• Fluid and food intake
- Lifestyle advice
Drug treatment5
Failure
Success in relieving bothersome LUTS:
Continue treatment
Detailed management

FIG. 146.2 Detailed management for persistent, bothersome lower urinary tract symptoms (LUTS) after basic management. *BOO,* Bladder outlet obstruction; *MIST,* minimally invasive surgical treatment; *OAB,* overactive bladder; *PSA,* prostate-specific antigen; *PVR,* postvoid residual; *Rx,* treatment. (Modified from McVary KT, Roehrborn CG, Avins AL, et al. Update on AUA guideline on the management of benign prostatic hyperplasia. *J Urol* 185(5):1793–1803, 2011.)

Validated questionnaires should be utilized to measure subjective outcomes for BPH and LUTS by documenting response to medical or surgical therapies. The AUA Symptom Score (AUA-SS), also known as the International Prostate Symptom Score (IPSS), is the most commonly used and should be obtained at each visit. An AUA-SS of 0 to 7 is considered mildly symptomatic, 8 to 19 is moderately symptomatic, and 20 to 35 is severely symptomatic. Flow rate and postvoid residual (PVR) are additional metrics that can supplement the history and physical examination. Cystoscopy should not be routinely performed unless it is being done to work up hematuria or evaluate whether the patient is a candidate for surgical therapy that is dependent on anatomic configuration. Per the AUA BPH guidelines (American Urological Association, 2011; McVary et al., 2011), urodynamics are considered optional and best suited for patients who demonstrate LUTS in which the diagnosis of BOO is unclear. Detrusor overactivity or detrusor underactivity is not a contraindication for surgical intervention of LUTS/BPH but must be evaluated in the context of the clinical situation and the patient appropriately counseled. Before surgical intervention, clinicians should consider assessment of prostate size and shape via abdominal or transrectal ultrasonography (TRUS), cystoscopy, or cross-sectional imaging (i.e., magnetic resonance imaging [MRI]/computed tomography [CT]).

Screening of men for prostate cancer has become a more controversial topic in recent years. The AUA BPH guidelines recommend the consideration of screening appropriately aged men with a life expectancy of greater than 10 years presenting with LUTS. **The most recent guidelines for the detection of prostate cancer recognized that the greatest benefit for prostate-specific antigen (PSA) screening is for men between 55 and 69 years of age** (Carter et al., 2013). This screening should include DRE and serum PSA if the patient so elects after an informed discussion. If the PSA is elevated, prostate biopsy should be performed before proceeding with surgical therapy. Clinicians should also be aware of the effect of different surgical therapies on PSA, as this may influence prostate cancer screening in the future. Although serum PSA has chiefly been used as a screening tool for prostate cancer, it may also be used as a surrogate for prostate volume, which can be a critical factor in the choice of BPH therapy. For this reason, we endorse its utility.

The goals for treatment should be used to guide the clinical evaluation. During the evaluation, the patient's voiding pattern should be assessed along with any medical conditions or medications that may affect voiding symptoms. The role of BPH in their overall voiding pattern should be assessed, particularly with respect to the possible benefits of any treatment. The necessity for treatment along with the probability of success of any treatment should be factored in and weighed against the risk associated with treatment. Finally, the physician's assessment along with the rationale should be explained to the patient using terms that the patient is able to understand.

Defining Outcomes

Response Rates

Subjective

Although verified questionnaire data have become customary in the reporting of symptoms, other data can be more open to interpretation. How severely a patient defines his or her dysuria or hematuria after a procedure can affect how he or she is included into what is often a binary scoring system defining the absolute presence or absence of a symptom. Clinicians should be aware of the effect of sham surgery on objective measures when comparing outcomes of BPH surgery arms. A systematic review of the literature has demonstrated a 27% improvement in AUA-SS and a 14% improvement in maximum urinary flow rate (Qmax) at 3 months after a sham endoscopic procedure (Welliver et al., 2015).

Objective

Although hopefully the most reproducible of results across studies, objective data are also dependent on accurate reporting and thus can be affected by many confounding variables. The most frequent confounders noted are the reporting of changes in patients with long-term follow-up. These data are prone to contamination from multiple sources including patients lost to follow-up and patients who are nonresponders and received additional treatment. Rarely are intent-to-treat analyses reported in series, and, in reality, the endpoints reported are generally those patients who are treatment “responders” who continued to return for future appointments.

Need for Secondary Procedures

The issues surrounding reporting of secondary procedures have been well delineated in previous versions of the AUA BPH guidelines. In summary, the defined metrics for re-intervention are generally rendered by the treating physician. These are difficult to classify as treatment may be triggered by subjective complaints, objective findings, or a combination of the two. **These thresholds can vary by patient or treating physician, and both same- study**

and cross-study reproducibility and reliability are challenging. Additionally, patients involved in trials may be more closely followed and carefully scrutinized causing both the patient and physician to change the threshold (in either direction) at which they may customarily initiate treatment. **Although treatment failures are clearly an important endpoint as they can lead to an increased overall cost in health care, the current literature can make these issues difficult to interpret clearly**.

Comparisons to Other Treatments

Comparing surgical procedures to each other and to medical management in an equitable way can be challenging. In particular, when comparing studies with an intervention (which by the nature of the intervention usually do not have a placebo) with those that use a placebo lead-in (common in medication studies), the former treatment will take full credit for the placebo effect and the true intervention effect, and the latter only for the true intervention effect. Although for the patient these outcomes may feel the same, the comparisons are inherently flawed.

When accepting any new procedure into the armamentarium of the urologist, studies generally begin with a small number of patients from a narrowly defined cohort. If success is seen there, then larger cohorts with more broad inclusion criteria follow. Frequently, these findings are compared with historical improvements and morbidities seen in early TURP data. These comparisons are somewhat unfair as they compare a current technology to a historical and often inferior data set. Studies making broad conclusions based on comparisons to historical controls should be viewed with skepticism.

If a technology truly appears successful, it moves on to the eventual RCT comparing the new technology to another treatment approach. Although the comparative effectiveness trial is a high bar to pass, caution must still be taken when interpreting these results. For instance, the comparison to TURP assumes that the surgeons performing the comparative technique are sufficiently trained and can produce predictable results.

Table 146.1**outlines expected complication rates based on the differing technologies.**Table 146.2**outlines expected outcomes in voiding parameters and is drawn only from RCTs. In constructing tables comparing the outcomes and complications, the inequalities of good, high level of evidence data comes to the forefront.** Many technologies have meta-analyses of large

RCT trials, and other included data were dependent on large case series. This is merely a sign of the available studies conducted. Although any comparison across technologies and time periods may be considered unequal, the authors attempted to use data from meta-analysis and RCTs filling in data from large series only when necessary.

TABLE 146.1

Expected Complication Rates after Endoscopic Benign Prostatic Hyperplasia Procedures

Presurgical Factors

Indications for Treatment

The most common indications for TURP have shifted considerably in the past few decades. Although this previously was voiding symptoms without formal subjective or objective quantification, we now recognize that the indication is more likely to be moderate to severe voiding symptoms attributed to BPH that are refractory to medical therapy. Questionnaires and objective data (e.g., uroflow, urodynamics/pressure flow) augment the history and physical examination before making the decision for surgical management of this condition.

Acute urinary retention (AUR) can often be indicative of an end-stage bladder. Although the presence of painful urinary retention at a low volume (<500 mL) may be considered a potentially positive sign for a nonatonic bladder, definitive assessment of bladder function can only be made definitively by pressure-flow studies. Taube and Gajraj reported on the amount of urine retained at time of catheter placement for AUR as a predictor of later successful void trial without surgical intervention (Taube and Gajraj, 1989). Of the 34 men who retained less than 900 mL, 15 were able to void, compared with only 2 of 29 men who retained greater than 900 mL of urine. In a patient who went into AUR triggered by medication ingestion such as α-agonists or anticholinergics, it is reasonable to initially place a catheter and allow time for the medication to leave the system with subsequent supervised decatheterization. In a patient with AUR caused by an inciting event such as postoperative or acute bacterial prostatitis, a similar plan can be utilized allowing the exacerbating incident to be treated or run its course. In the community-based Olmstead County Study (Jacobsen et al., 1997), 57 of the 2115 men studied developed AUR. One-half of these episodes of AUR were related to surgical procedures, and ultimately only 8 of these 57 patients required TURP within 6 months of the incident. The addition of an α-blocker during a spontaneous episode of AUR leading to catheterization is commonly used and has been shown to increase the percentage of patients subsequently passing a voiding trial from 47.9% to 61.9% ($P = .012$) when compared with placebo (McNeill et al., 2005).

Recurrent and robust gross hematuria is a legitimate indication for treatment of the prostate once other causes (e.g., infection, carcinoma, trauma) have been excluded. This may be done as either a scheduled case in the recurrent patient or done in the acute setting in a patient presenting for clot retention or continued hemorrhage despite more conservative management options (Borth and Nickel, 2006). The use of 5ARIs may also be of use in a patient with repeated episodes that are not serious enough to require surgical intervention (Foley et al., 2000).

The findings of **bladder calculi, bladder diverticula,** and other signs of end-stage bladder decompensation are also possible indications for surgical intervention provided medical management has been previously attempted. **Recurrent urinary tract infections** resulting from an elevated PVR urine is also an indication for considering intervention after bacterial prostatitis (both acute and chronic) has been excluded as a possible source of these infections. A bladder diverticulum is not an absolute indication for surgery; however, surgical intervention may be warranted if the diverticulum is associated with recurrent UTI or progressive bladder deterioration. Although classically an indication for surgical treatment of BPH, the most recent AUA BPH guidelines state that bladder calculi themselves should be treated when diagnosed, and a trial with medical management may be considered once the calculi have been removed.

Bilateral hydronephrosis with renal functional impairment requires relief of the obstruction with the paramount goal to preserve the upper tracts and renal function. With catheterization and relief of obstruction, a postoperative diuresis may ensue. If the level of obstruction is confirmed at the bladder outlet, the treating physician should only proceed to definitive care after the patient's general medical condition has been optimized and any sequelae of the obstruction (e.g., impaired renal function, edema) have been fully evaluated or have returned to baseline status. In the case of bilateral hydronephrosis (or elevated serum creatinine) unrelieved by catheter placement, additional studies should be considered. In patients with long-standing BOO leading to a hypertonic and thickened bladder, the ureters could be obstructed at the level of the bladder, and ureteral stenting may be required. As routine screening for upper tract dilation is not currently recommended in patients with BPH, the urologist should continue to consider its presence in these settings. Sarmina and Resnick (1989) documented previously unrecognized renal failure in 3.7% of the 909 men treated for BPH between 1980 and 1986. They estimated that greater than 5% of men with unrelieved BOO related to BPH would have chronic renal insufficiency and concluded that risk would be higher in those with a history of enuresis, UTI, urinary retention, and a history of symptoms for more than 1 year.

An elevated or increasing PVR has been postulated as a possible indication for surgical intervention. However, the urologist should remember that there can be significant variability in this value when assessed over time (Bruskewitz et al., 1982). The above, “classic” indications for BPH treatment are still relevant, and under these circumstances, it is reasonable to forego a trial of medical or conservative therapy and proceed directly to surgical intervention. However, patients should generally be trialed on medical management before proceeding to surgical intervention. Once patients have “failed” medical management, they should be considered for surgical therapy to relieve obstruction and improve LUTS and overall quality of life (QoL). Surgery is considered for patients with moderate to severe symptoms (AUA-SS >8) and who have failed appropriate medical management (McVary et al., 2011).

Although the validated AUA-SS is an important questionnaire for the urologist when evaluating a patient with LUTS, it does not completely replace a careful history as it is not diagnostic of LUTS/BPH. The symptom characteristics that the patient reports should carefully be defined both through the use of an AUA-SS and history; surgery should be used carefully in patients with predominant storage symptoms unless these symptoms are thought to be a result of problems emptying the bladder.

OP was the mainstay of treatment for LUTS/BPH for decades and is still an excellent treatment option. Although covered in detail elsewhere in this text, this treatment is useful in men with very large glands, which still may be a challenge for endoscopic treatment and for men who need treatment for large or multiple concomitant bladder calculi or diverticula.

Antibiotic Coverage

Antibiotic coverage for surgery should be carefully considered for each patient with reference to the AUA Best Practice Statement (Wolf et al., 2008). The minimum coverage would include either the use of a fluoroquinolone or trimethoprim/sulfamethoxazole. However, if the patient has an indwelling catheter (urethral or suprapubic), then extended coverage should be considered.

Sepsis is still an occasional occurrence after TURP, and antibiotics should be carefully selected. One European series with 857 patients had a bacteremia/septic shock rate of 2.3% (Vivien et al., 1998). Risk factors for bacteremia/sepsis included preoperative bacteruria and surgery longer than 70 minutes. The center where the surgery was performed was noted to also be a risk factor, implying that surgeon factors such as antibiotic choice or technique may be a factor.

The practice of extended antimicrobials is supported by the frequency with which patients with indwelling catheters have a positive (and often polymicrobial) urine culture (Warren et al., 1982). The spectrum of these organisms is variable with factors like local patient population, facility specifics, and previous antimicrobial treatment all affecting the latent organisms. Additionally, patients with long-term catheters are often exposed to antimicrobials, and they may have an increased risk for resistance (Bjork et al., 1984).

Histologic Specimen

In an era before PSA screening, prostate cancer was frequently diagnosed by the examination of the pathologic specimen obtained during TURP. With the increase in many treatment options that do not procure a specimen, there is some concern that we may be missing clinically significant cancers. The advent of common PSA screening was shown to decrease incidentally found cancer from 12.9% to 8.0% in one series (Mai et al., 2000). In a series looking at a 13-year period around the time of incorporation of PSA screening, Tombal et al. (1999) found a decrease in all T1 cancers from 23% to 7% of specimens from BPH treatments, with a greater effect on T1b disease (decrease from 15 to 2%). Patients with incidentally found prostate cancer during TURP were more likely to have organ-confined disease and lower Gleason scores than men detected by prostate biopsy (Helfand et al., 2009). A study from Meeks et al. (2013) concluded that in men with a PSA less than 4 ng/mL, the risk for finding a clinically significant cancer would occur in only 1 of 382 TURPs, making up a total of 390 such cancers detected nationally in a 3-year period. In a pool of 60,000 LASER vaporizations, 163 clinically significant cancers would be missed. Taken in concert, these studies report that in men who have undergone adequate PSA screening, relatively few clinically significant prostate cancers will be missed by using a technology that does not obtain a pathologic specimen.

Matching Treatment with Patient

Multiple patient factors may lead the urologist to recommend a particular treatment option for a patient as each treatment has its own inherent risk, benefit, and safety profile. Some patient factors to consider are prostate size, previous surgical intervention, history of urinary retention, inability to stop ongoing anticoagulation, surgeon experience, and, of course, patient preference. Factors more specific to the surgeon would include surgeon experience with different treatments and their availability at that institution. Historically, the urologist used a DRE or cystoscopy to estimate prostate size. DRE has been found to overestimate small glands and underestimate large ones, even in the setting of an experienced gray-haired endoscopic savant. During cystoscopy, each centimeter above the normal 2.5-cm prostate length would roughly equate with an additional 10 g of additional prostate weight. Although these may give the treating physician a general idea of prostate size, these types of assessments have been shown to be inaccurate. **If gland size may lead the urologist to choose between two different treatment techniques, the patient may be well served by undergoing an office TRUS to precisely assess prostate size before deciding on the surgical intervention.** Most urologists have an algorithm wherein they use prostate volume to dictate their recommendation for surgical intervention, with a very large gland leading the urologist to a bipolar TURP or OP and a smaller gland leading toward LASER or photoselective vaporization (PVP). However, more and more data are being generated showing efficacy of LASER methods in larger glands as is discussed in the PVP (LASER TURP) section of text. The authors of this chapter prefer the use of LASER TURP for glands less than 100 cc, with bipolar TURP for glands between 100 to 150 cc and simple prostatectomy (open or robotic) for glands larger than 150 cc. Regardless of the specific cutoffs used for each technology, it is a wise urologist who adheres to the AUA BPH guidelines suggestion that the choice of approach should be based on the patient's individual characteristics, including anatomy, the surgeon's experience, and discussion of the potential benefit and risks for complications (American Urological Association, 2011; McVary et al., 2011).

Additional factors that may also lead toward the use of conventional loop resection over LASER treatment may be the presence of a median lobe or a ring of intravesical prostate. The use of a loop in this situation may be preferable as it allows a less experienced surgeon the option to reach out and “pull” the protruding prostate away from the bladder wall during resection.

With increasing age and comorbidity, patients may now frequently be on anticoagulation when the urologist recommends surgical therapy. The inability of these patients to come off of their anticoagulation may lead the urologist to a difficult decision with regard to treatment options. Patients who are unable to cease anticoagulation for surgery may frequently be counseled that a treatment like LASER TURP may limit their surgical risk as this technique appears to have improvements over TURP in terms of bleeding risk.

Key Points

- Patients should generally be trialed on medical management before proceeding to surgical intervention. Patients failing medical management may be considered for surgical therapy.
- Perioperative antibiotic coverage should not be neglected as serious adverse outcomes still occur.
- Both patient and physician factors should be considered when selecting the appropriate surgical treatment for patients.

Specific Technologies

Non-LASER Options

Monopolar Transurethral Resection of the Prostate

TURP involves an endoscopic approach via the patient's urethra to surgically remove the inner portion (primarily the transition zone) of the prostate that encircles the urethra. An electrified wire loop is used to remove the portion of the prostate between the bladder neck and the verumontanum to a depth of the surgical capsule. The current is carried from the cutting loop through the tissue (and patient) to the return electrode in the grounding pad. Although still considered the gold standard for BPH treatment, the morbidity associated with the procedure has led to the development of many endoscopic alternatives to the classic monopolar transurethral resection of the prostate (M-TURP).

The original M-TURP requires the use of a non-ionic irrigant (glycine, sorbitol) to carry the current through the cutting loop into the tissue (and through the patient) to the grounding pad electrode. Unfortunately, these non-ionic solutions are hypo-osmolar and can be problematic when absorbed through open prostate sinuses into the systemic circulation, leading to acute dilutional hyponatremia (TUR syndrome). The migration of monopolar to bipolar energy has produced a considerable improvement in the safety profile of TURP. The use of iso-osmolar saline in bipolar TURP has reduced the incidence of TUR syndrome.

Technique (from Preoperative Area to Recovery Room)

Preoperative.

TURP is generally performed under general or spinal anesthesia. Traditionally, TURP was accomplished with the patient under spinal anesthesia so the anesthesiologist could monitor for signs of TUR syndrome caused by hyponatremia. However, this practice has become less commonplace for this indication, but the method remains useful. After adequate anesthesia has been initiated, the patient is positioned and secured in the dorsal lithotomy position and padded appropriately to prevent positioning injury, with special attention paid to the patient's legs. **The patient's buttocks should be placed near the table edge so that the table does not impede the full course of the scope. If**

not positioned far enough down the table, the anterior portions of the prostate may be difficult to reach, particularly in patients with fixed pelvic anatomy from previous pelvic injury, orthopedic history, radiation, or trauma. Adequate antibiotic coverage should be given as detailed earlier in this chapter. A quick abdominal examination will provide a baseline for any subsequent intraoperative examination should a perforation occur during the case leading to prevesical irrigant accumulation. Shaving of the genitals and perineum is not required, and any variety of standard skin preparations may be used on the lower abdomen, genitalia, and perineum. If required, a grounding pad should be placed on the leg outside of the surgically prepped area and a pad placed on the contralateral leg to any previous joint replacement surgeries. Use of the O'Conor type rectal shield provides ready, sterile access to the rectum in case the prostate needs to be lifted anteriorly for resection. Irrigating fluid should be maintained at body temperature and placed at the lowest height relative to the patient to provide adequate visualization. **Fluid level may be raised during the case if visualization becomes obscured by bleeding.**

Intraoperative.

Before the resectoscope is inserted, it should be assembled to make certain all elements are appropriately fitted and in working order. The use of a video camera mounted to the lens is largely standard at this point as few urologists prefer to place their eye directly to the lens. Some urologists prefer an instrument that permits a continuous flow of irrigating fluid. This can be done in either a passive mechanism into the cystoscopic drape or with the aid of a machine that allows for active removal of fluid from the bladder.

The plan for resection can be varied by any number of patient factors, and in general the best approach is the one best practiced and understood by the urologist. Despite the multiplicity of approaches, some generalizations are proposed later in this chapter with the consideration that the surgeon should always take an organized and systematic approach.

Before beginning to resect, the bladder should be inspected for any bladder pathology (e.g., tumor, diverticula). The presence of an unsuspected bladder tumor may necessitate a change in plan with resection of the bladder tumor at that time and return for TURP in the future once pathologic staging is complete. **The bladder neck, trigone, and position of the ureteral orifices, verumontanum, and external sphincter should be noted, and their relationship to the prostatic adenoma confirmed.** If the surgeon has difficulty identifying the ureteral orifices, indigo carmine may be given intravenously by the anesthesiologist with the efflux seen coming from the orifices a few minutes later. The type of irrigant used is based on the type of resection planned but generally is either normal saline (for bipolar resections) and glycine or water (for monopolar resection). **In situations in which the cutting element does not seem to be functioning, there is a general algorithm to check: Check the connection to the scope and generator; inspect the irrigating fluid to verify that it is commensurate with the generator technology being used; and, if a monopolar technology is being used, check that the patient is properly grounded.** The opening of the procedure should start with resection of any impediment to movement of the irrigating fluid. The presence of a middle lobe should lead the surgeon to start the resection there. The numerical choice of current is also dependent on the surgeon's preference, but mixed currents generally provide great hemostasis with less cutting ability. Once a median lobe has been removed, the lateral lobes of the prostate may then be tackled by the resectionist.

When resecting the lateral lobes, some surgeons prefer to resect the floor of the prostatic urethra initially (between the 5 o'clock and 7 o'clock positions), and others use a modification of the Nesbit “encirclement” approach (Fig. 146.3) (Nesbit, 1943). In the Nesbit approach, resection is initiated at the 11-o'clock to 9-o'clock and 1-o'clock to 3-o'clock positions. The resection exposes but does not resect the bladder neck fibers and carries the resection proximally to the base of the verumontanum and avoiding any injury to the external sphincter (Greene, 1979; Thompson, 1975).

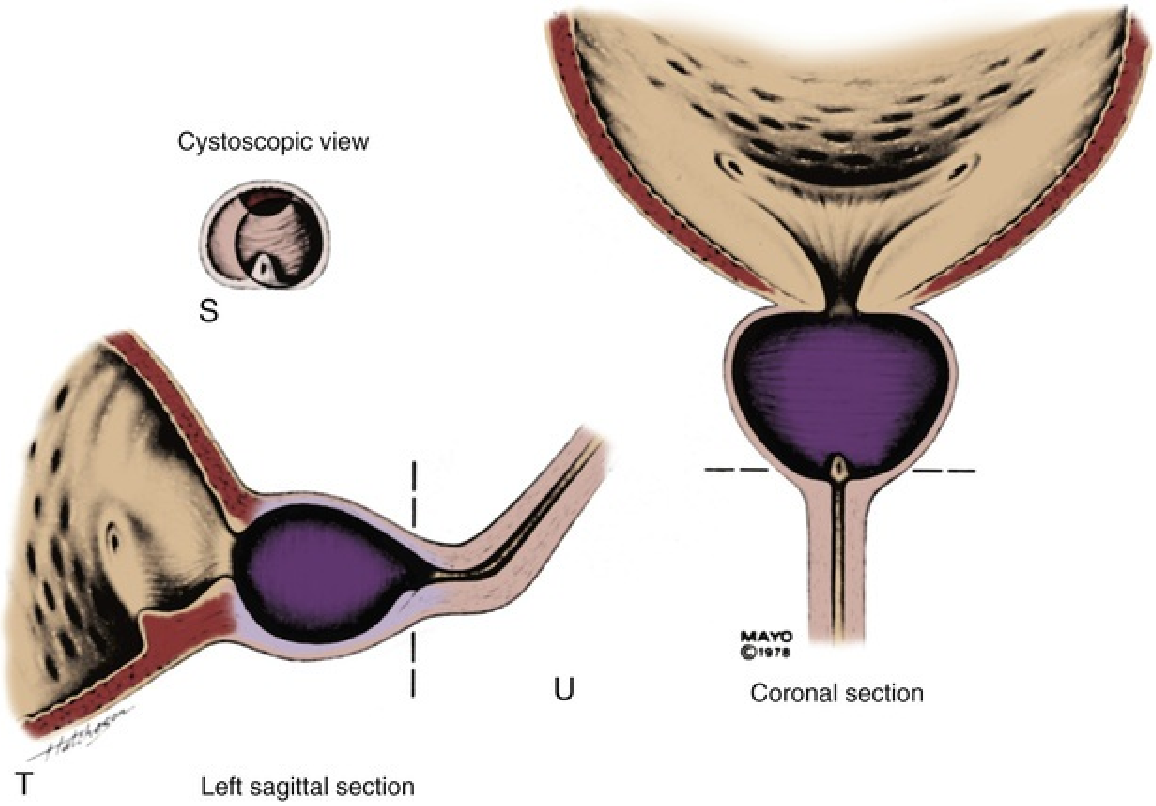

FIG. 146.3 Approach to transurethral resection of the prostate by starting the resection anteriorly. (A to C) First stage of resection of the prostate. The resection is begun at the 12 o'clock position, and the tissue at the bladder neck and the adjacent adenoma are resected in quadrants. (D) The midportion of the gland is resected starting at the 12 o'clock position and carried down to the 9 o'clock position. (E and F) Sagittal and coronal sections are shown. (G) The resection is now begun at the 12 o'clock position, and the left side of the patient's gland in the midfossa is resected down to the 3 o'clock position. (H and I) Sagittal and coronal sections are shown. (J) The midportion of the gland is resected farther down from the 9 o'clock position to the 6 o'clock position. (K and L) Sagittal views. (M to O) The tissue remaining at the apex is now resected. Resection is initiated next to the verumontanum and carried toward the 12 o'clock position. (P to R) Residual tissue is carefully cleared on the patient's right side. (S to U) The remaining residual tissue is cleared from the patient's left side, leaving an unobstructed view from the verumontanum through the bladder neck into the bladder. (©1978, the Mayo Foundation.)

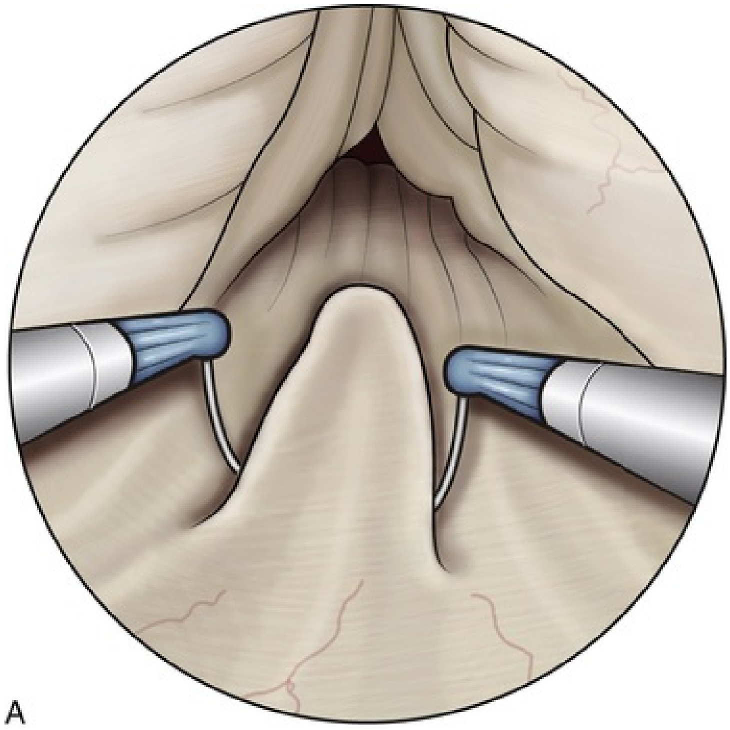
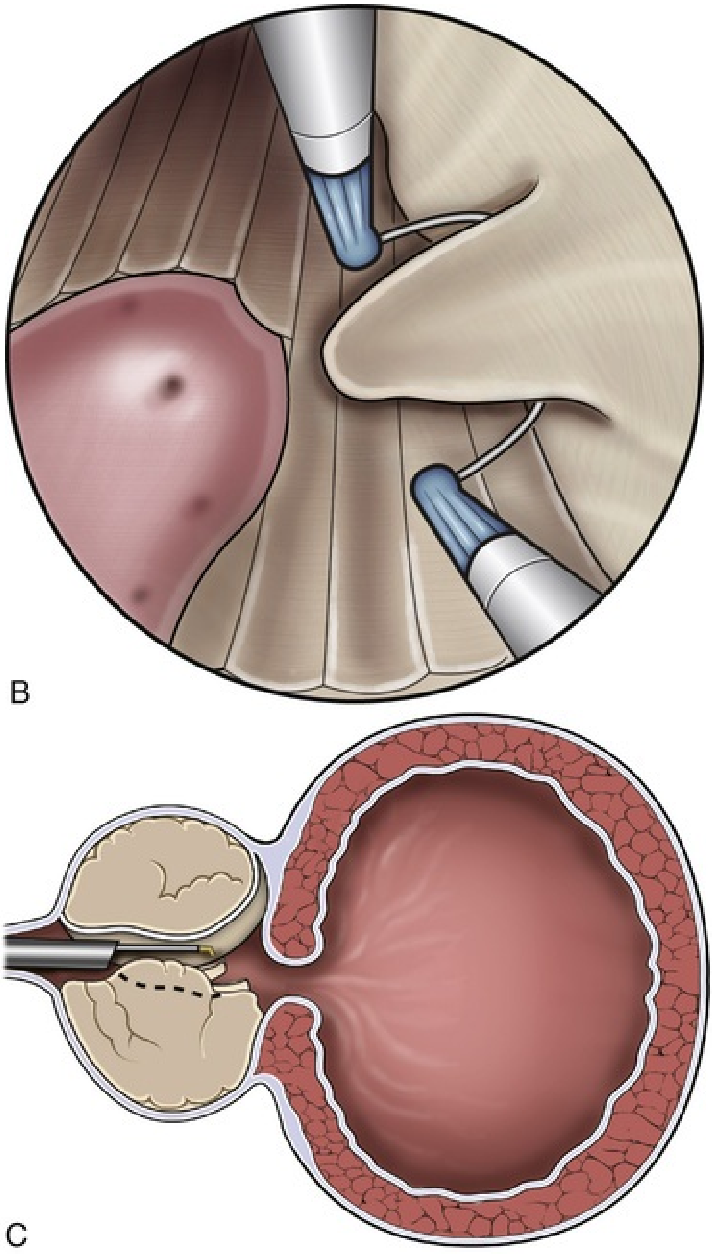
Surgeons starting with the prostatic floor generally start by resecting a "channel" at either the 5 o'clock or 7 o'clock position and resecting down to the surgical capsule of the prostate (Fig. 146.4). By finding the surgical capsule early in the procedure, the depth of the resection is set. The channel is then widened (usually laterally) and then carried up the lateral walls toward the anterior aspect of the prostate following the surgical capsule as the depth of resection. The resectionist may note that the lateral lobes will begin to “fall” into the fossa as they are resected, making subsequent resection easier. Ultimately, the area between the 5 o'clock and 7 o'clock positions is then resected at the final stages of the procedure to smooth out the prostatic floor and finish the procedure without undermining the bladder neck during multiple movement of the scope.





B
C

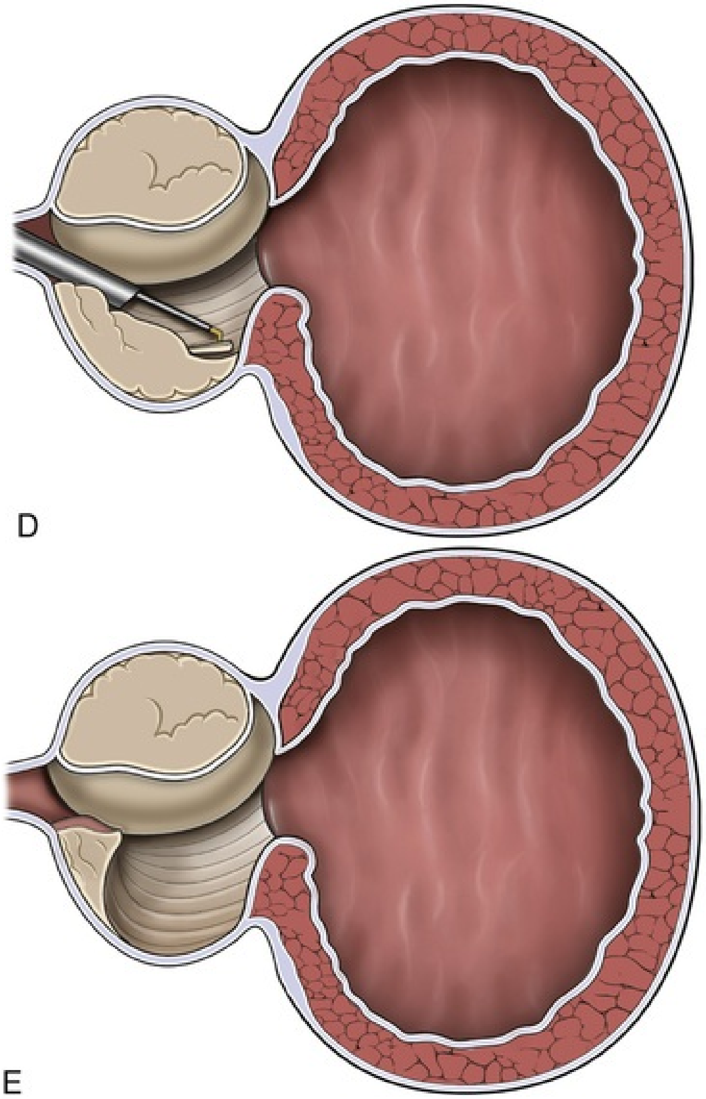


FIG. 146.4 Approach to transurethral resection of the prostate starting with the prostate floor. (A) View from resectoscope with an electrosurgical loop resecting prostate floor. (B) Resecting a lateral lobe. (C) Sagittal view of resection of the prostate floor. (D) Continuing resection down to the capsule. (E) Completed resection of this section of prostate, leaving some residual apical tissue to avoid injury to the external sphincter. (Modified from May F, Hartung R. Surgical atlas: transurethral resection of the prostate. *BJU Int* 98(4):921–934, 2006.)

In either resection schema, the initial stages of the resection should involve long, smooth tissue cuts. The produced prostate chips should be long and "canoe-like" in appearance with a length equivalent to the extended resection loop. A synchronized, rocking motion with the resectoscope allows the resectionist to follow the prostate shape and achieve the desired chip shape and resection. One should avoid cutting chips of insufficient length or thickness as this is inefficient and may lead to an irregular resection bed that hides bleeding areas. As the resection progresses, the surgeon may need more deliberate pressure on the resectoscope to reach more lateral and anterior aspects of the prostate. In surgeons utilizing the O'Conor shield, digital elevation of the prostate may aid in resection. Generally, aggressive resection of the anterior and apex of the prostate are postponed until the end of the procedure. The anterior aspect of the prostate fossa has the least depth of adenoma and is easily perforated. Additionally, the sphincter has a slight tilt with the anterior portion of the sphincter being the most proximal in the urethra. Although emptying the bladder may allow this anterior portion to become more visible to the surgeon and aid in resection, adequate fluid should be kept in the bladder to avoid inadvertent bladder perforation with the loop extended.

Overresection (including capsular perforation) in any area before the major portion of the adenoma has been removed may expose large venous sinuses. Exposing these sinuses will predispose to bleeding and fluid extravasation/absorption and compromise the resection and patient outcome. **The prostate apex is best resected at the end of the procedure in a bloodless field, where resection can be done precisely to avoid injury to the external sphincter.** A finger placed in the rectum via the O'Conor shield may also aid in resection at the apex. A limited amount of residual tissue may be left near the verumontanum as it is certainly preferable to repeat the procedure than to make the patient incontinent with an overzealous resection near the apex.

Hemostasis should be maintained throughout the procedure. Arterial bleeding is characterized by its bright red color and persistence, even with irrigation running over the area of hemorrhage. Additionally, this type of bleeding will persist during filling and drainage of the bladder. Arterial bleeding should always be controlled, and precise fulguration is paramount. If vision is obscured, the cutting loop may be advanced to place the loop on an area of bleeding with the fulguration current and then used to control the arterial end. “Ricochet” or “bounce” bleeding from the opposite wall or a cryptic bleeding site that requires further, deeper resection should also be kept in mind (Greene and Holcomb, 1979). Identifying bleeding at the bladder neck (particularly anteriorly) can be facilitated by nearly emptying the bladder.

Venous bleeding can be more vexing and generally appears darker in color than arterial bleeding. Venous bleeding will often disappear with a full bladder as it applies pressure to the prostatic fossa. Identifying venous sinuses may be difficult because of the lack of persistent bleeding with rapid irrigation influx, and controlling of the bleeding with fulguration may be even more challenging. Once again, the cutting loop may be used to temporarily tamponade any bleeding with precise fulguration. If the venous bleeding cannot be completely controlled (as is frequently the case), a catheter may be inserted and the balloon overinflated and pulled to traction for tamponade of venous bleeding.

Before the operation is terminated, all tissue must be removed from the bladder with careful attention paid to make sure prostatic chips have not fallen into any bladder diverticulae that may exist. An Ellik or Toomey syringe may help facilitate removal of any tissue. The prostatic fossa should be examined again as one of the final steps with control of any arterial bleeding. A large-bore catheter should be carefully placed into the bladder with the use of a wire catheter guide if required. The amount of fluid placed in the balloon should be tailored to the volume of resected tissue to avoid the catheter balloon falling into the excavated prostatic fossa. In our practice, the Foley catheter is generally placed to traction for a short time with release of traction based on residual hematuria. The use of continuous bladder irrigation (CBI) is not compulsory but can be used if the irrigant is not clear at the end of the case.

Placement of a three-way catheter at the end of the case does not commit the patient to CBI as the inflow port can always be obstructed with a catheter plug. If CBI is elected, skilled nursing is preferable as an unrecognized obstruction to the outflow tract can lead to bladder distension and a worsening of bleeding. Intermittent irrigation may also be used but requires extra attention to the inflow/outflow patterns.

Postoperative Care.

Most patients undergoing TURP have an uneventful postoperative course (Mebust, 1993). The diet can quickly be advanced in the postoperative period, and the patient may ambulate on the day of surgery if there is a mild degree of hematuria. When ordering postoperative fluids, one should remember that even an uncomplicated resection has fluid absorption between 800 mL and 1000 mL (Oester and Madsen, 1969). Patients with persistent complaints of bladder spasms or rectal discomfort should prompt the clinician to examine the catheter to make sure it is not obstructed.

In the absence of significant capsular perforation or persistent bleeding, the catheter can be removed in 24 to 48 hours. If minor bleeding persists beyond this timeframe, the patient may be discharged to home with the catheter in place with close outpatient follow-up. Although a wide variety of practice patterns exist, patients may be discharged to home with or without the catheter, and we generally discharge patients on postoperative day 1. The use of narcotics for pain control is almost never necessary, and they should be avoided at discharge.

The use of stool softeners in the postoperative period (extending out 1 month from surgery) is likely beneficial as passage of hard, impacted stool may precipitate bleeding. **Patients should avoid activities that place excessive or uneven pressure on the perineum (e.g., horse riding, use of a riding lawnmower) for 4 to 6 weeks to avoid inciting any postoperative bleeding while the freshly resected prosthetic bed re-epithelializes.** Epithelialization of the prostate bed occurs by migration and proliferation of transitional cells for the resected margins. This usually requires a few weeks, and patients will frequently report dysuria during this time. **The long-term use of phenazopyridine is discouraged but may help patients overcome this dysuria in the immediate postoperative period.** Patients should be warned that this medication may make bodily fluids appear red-orange in color and can stain contact lenses. To alleviate patient anxiety when this occurs, patients should be warned that they will frequently pass tissue or eschar with some minor, delayed bleeding 1 to 4 weeks from the time of the procedure. It is our practice to have the patient refrain from any sexual activity as concern arises about precipitous bleeding, even though this is clearly a matter of expert opinion.

Patients with long-standing obstruction (particularly those with urgency and frequency preoperatively) will often experience a continuation or exacerbation of these symptoms in the postoperative period. If proper bladder emptying can be verified, an anticholinergic or beta-3 agonist medication during this time may help the patient feel more comfortable. It is our practice to warn those men with preoperatively documented detrusor overactivity that patience will be required in the months after surgery to see if this will resolve. Such caution goes a long way in assuring patients to adopt a strong coping mechanism rather than a polypharmacy approach.

Outcomes.

Although morbidity data for men after TURP is commonly cited in a negative fashion, these data should not detract from the large number of men who benefit from the procedure. The number of patients who judge their voiding symptoms to be “better” or “much better” depends partly on the initial severity of symptoms and duration of follow-up but is generally

above 75% and can be as high as 93% (Bruskewitz et al., 1986; Fowler et al., 1988; Lepor and Rigaud, 1990). The review by the Agency for Health Care Policy and Research (McConnell et al., 1994) indicated an overall symptomatic improvement of 88% for TURP. These data review indicated that surgical procedures in general (OP, TURP, TUIP) produced about an 80% improvement in symptom scores compared with 30% to 40% range for placebo and nonsurgical therapies.

The large, multicenter Veterans Administration study was conducted before the common use of medical treatment for BPH and compared TURP and watchful waiting (Wasson et al., 1995). TURP was considerably more effective than watchful waiting in improving symptoms and avoiding treatment failure. More substantial benefit was noted in men with severe urinary symptoms as men with substantial bother had a 91% chance of improvement compared with 62% in those with less significant bother.

Considerable and durable changes in AUASS, QoL score, Qmax, and many other voiding and lifestyle metrics have been observed with TURP. Masumori et al. (2010) showed the procedure's symptomatic durability in their analysis of patients available at 12 years after TURP. Although patients started out with an overall fairly low AUA-SS (16.7), they improved by 75% at 3 months postprocedure. The difference was less pronounced (40% decrease compared with baseline) but still statistically significant at 12 years. QoL scores followed a similar pattern, with a 67% decrease at 3 months compared with baseline, which was still significant but less pronounced (52%) at 12 years. The patients with confirmed BOO by pressure-flow study performed better than those without this finding. Patients with urodynamic study (UDS) findings of detrusor overactivity or underactivity did not differentiate themselves with regard to change in AUA-SS compared with the rest of the cohort. Analysis 7 years after M-TURP found an improvement in Qmax of 106% at 1 year, with a 28% improvement at 7 years (Nielsen et al., 1989). Of the 44 patients still able to be evaluated at 7 years, 16% required repeat resection.

Recent data on M-TURP generally needs to be drawn from the procedure as the control group in RCTs. In general, marked reductions in AUA-SS and QoL scores are seen with significant improvements in Qmax and UDS parameters. An increase in Qmax from 125% to 175% and a reduction in AUA-SS of 75% are frequently seen. Additionally, rarely does a competing technology have a lower risk for BPH-specific retreatment.

In RCTs examining comparison of TURP to other treatments for

LUTS/BPH, TURP is generally at least equivalent if not superior in terms of outcomes focusing on improvements in voiding, with most other treatment options having better safety and adverse-event profiles.

TURP in the Anticoagulated Patient.

A controlled study by Dotan et al. (2002) looked at patients undergoing bridging with low-molecular-weight heparin and early resumption of warfarin after stopping warfarin 5 days preoperatively. The average change in hemoglobin was not statistically different, and although the study group did more frequently require transfusion, this difference was also not significant.

Chakravarti and MacDermott (1998) utilized a different strategy with patients in which they only underwent a 2-day cessation of warfarin before surgery with intravenous heparin substitution during cessation. Of the 11 patients studied, they had a modest decrease in hemoglobin (1.6 g/dL) with surgery, with 3 patients readmitted within 30 days for bleeding issues.

In a multicenter study of 612 patients, 33% were on blood thinners before surgery (55 on warfarin, 74 on clopidrogel, and 62 on aspirin) (Descazeaud et al., 2011). All patients discontinued warfarin and clopidrogel for surgery, with most patients getting bridged until surgery with some form of heparin. Only three patients continued their aspirin through surgery, with the majority of those stopping aspirin also getting a heparin bridge. **Follow-up at 3 months demonstrated that anticoagulated patients had a higher rate of transfusion (1.9% vs. 1.0%, *P* = .026), bladder clots (13% vs 4.7%, *P* < .001) and thromboembolic events (2.4% vs. 0.7%, *P* = .02). Follow-up studies have found differing results** (Raj et al., 2011; Taylor et al., 2011).

A dose-escalating, randomized, double-blind, placebo-controlled trial on a heparinoid medication showed a dose-dependent increase in blood loss when given during the time of TURP. Bleeding was so significant at the highest dose that the study was stopped prematurely (ten Cate et al., 1987).

Aspirin has also been studied in the perioperative period. A well-designed prospective, randomized, double-blind, placebo-controlled study looked at patients randomized to 150 mg of aspirin or placebo for 10 days before TURP. With no difference in intraoperative blood loss, the aspirin group had a significantly higher postoperative blood loss. Although there was no statistical difference in transfusion requirements, more units of blood were used in the group on aspirin (Nielsen et al., 2000). Two older, controlled studies concluded there was no difference in blood loss for patients continuing aspirin therapy through surgery (Ala-Opas and Grönlund, 1996; Thurston and Briant, 1993).

In summation, the risk associated with TURP in the anticoagulated patient is significant, and authors have postulated that LASER options may be preferable in patients who are unable to come off of anticoagulation for surgery (Descazeaud et al., 2009).

Complications.

Despite decades of use, M-TURP still has a considerable intraoperative complication rate. Although the overall complication rate has improved, there is **still at least a 3% chance of intraoperative complication** (Ahyai et al., 2010) **primarily from hemorrhage leading to transfusion.** However, with other MISTs requiring more frequent reoperation, the perioperative and late complication rates of M-TURP continue to make it a viable option in the correctly chosen patient. The overall morbidity of TURP continues to approach 20% when studies include blood loss requiring transfusion, infections, strictures, sexual dysfunction, urinary incontinence, urinary retention, and the development of TUR syndrome (Borboroglu et al., 1999; Mebust et al., 1989).

Intraoperative and Perioperative Problems.

There is always the possibility of absorption of the irrigating fluid into the patient's systemic circulation during resection of prostatic tissue, and **TUR syndrome does still occur**. Much of our current understanding of the etiology of TUR syndrome starts with work from the 1950s (Hagstrom, 1955; Harrison et al., 1956). **The prostatic venous system has a pressure of approximately 10 mm Hg, and fluid at a pressure exceeding this will lead to fluid absorption when these vessels are exposed during resection.** The absorption of the hypo-osmolar irrigating fluid leads to an acute dilutional hyponatremia with resulting neurologic changes (confusion, nausea, vomiting, visual changes, hypertension, tachypnea, and bradycardia). Now with the use of isotonic, iso-osmolar irrigating solution and the bipolar electroresection system, this risk has theoretically been eliminated. **TUR syndrome was seen in 2% of cases in the AUA cooperative study** (Mebust et al., 1989)**. Larger glands (greater than 45 g) and longer resections (greater than 90 minutes) were risk factors.** The recent meta-analysis of RCTs found a lower incidence, with only 0.8% of patients suffering from TUR syndrome (Ahyai et al., 2010). Although most authors agree that TUR syndrome is caused by dilutional hyponatremia, there have been alternate etiologies proposed. Hoekstra et al. (1983) and Ryder et al.

(1984) noted elevated serum ammonia levels after glycine irrigant resections. Excessive glycine absorption led to liberation of ammonia from metabolic pathways leading to immediate or delayed encaphalopathic symptoms.

Several steps can be taken to prevent this complication. Use of a bipolar resection method should certainly be considered. **The height of the irrigating fluid above the patient should be carefully chosen.Madsen and Naber** (1973)**demonstrated that the ideal height of the fluid was 60 cm above the patient. From their work, this appears to be the minimal height to maintain good vision but also not lead to excessive systemic fluid absorption.** Increasing the height 10 cm above this leads to increased pressure in the prostatic fossa and a greater than twofold increase in systemic fluid absorption. Diagnosis of this condition is made by assessment of neurologic status and comparison to laboratory values. Serum sodium should be obtained in long, large resections postoperatively (or intraoperatively if concern exists). A serum sodium of less than 120 mEq/L indicates a significant dilution and may lead to coma or seizures. Transient visual disturbances or blindness indicate central nervous system (CNS) toxicity and are obviously very distressing to all the parties involved.

If profound CNS symptoms are noted, judicious administration of hypertonic saline should be instituted, and formulas exist to help guide this resuscitation as overly rapid correction of hyponatremia may lead to a demyelinating lesion of the brain (central pontine myelinolysis).

In either resection approach, the scope may need to make multiple trips across the prostatovesical junction leading to trigone undermining. If during initial resection the dorsal aspect of this junction becomes overly resected, these trips may become more challenging as the scope is forced to move “uphill” and increase the detachment of the trigone from the posterior prostate base.

Ureteral injury is an uncommon complication. Identification of the ureteral orifices should be attempted before resecting. The 70-degree lens and intravenous injection of an agent that colors the urine (methylene blue, indigo carmine) may be of aid in identifying the ureteral orifices. If still unable to identify them because of a high bladder neck or large median lobe, resection should begin in the midline, taking down the median lobe as described earlier. After this is accomplished, the ureteral orifices may become more apparent to the resectionist without the mass effect of the median lobe obscuring the view.

Hemorrhage in the resected area is a common complication both during and after TURP. Every effort should be made to achieve hemostasis during the operation to prevent the need for a return to the operating room. The risk associated with transfusion in patients undergoing TURP is low but still occurs, and patients should be counseled appropriately. Ideally, hemorrhaging areas are controlled as the procedure is ongoing. **Arterial bleeding should generally be fulgurated during the procedure, although the resectionist may continue to resect arterial bleeding until the capsule is exposed and fulgurate a bleeding vessel at this level. This practice should be engaged in carefully but is reasonable**. Venous bleeding is classically more difficult to control. Fulguration of open venous sinuses should be attempted, but this may be ineffective, even in the most trained hands. In these cases, balloon tamponade may be most effective. Once arterial bleeding has been controlled, a large balloon (30 mL) Foley catheter may be placed with 50 to 60 mL of water placed in the balloon. The catheter may then be put to traction for a short time to see if this relieves bleeding. In certain cases, it may be prudent to continue traction overnight. The Veterans Affairs Cooperative Study of 3885 patients found a **transfusion rate of 2.5%** (Mebust et al., 1989). Other early data reported high transfusion rates with over 20% of patients receiving transfusion (Doll et al., 1992), and more **recent data from an analysis of RCTs found that 4.4% of patients would require transfusion** (Mayer et al., 2012).

Perforation may occur at many places during the resection; the prostatovesical junction, prostatic capsule, or the bladder itself are all possibilities. The electroresection itself or overdistension of a thinned area of the prostatic capsule may lead to frank perforation with visual evidence often being subtle. The glistening fat of the periprostatic or perivesical spaces is usually a telltale sign of perforation. In unclear cases, cystography (with drainage films) may be used to assess the degree of perforation and the drainage pattern. **Extravasation related to prostatic resection is almost always extraperitoneal.** If bladder perforation occurs near the dome, then cystography should be considered to rule out an intraperitoneal rupture, which would require open closure. Extraperitoneal rupture caused by resection with limited extravasation can almost always be managed with extended catheter drainage and careful observation. In cases of extraperitoneal rupture occurring with extensive extravasation, percutaneous or open drainage may be required.

Persistent penile erection may develop at any point during the case and may drastically limit the mobility of the resectoscope. Detumescence may occur spontaneously without active management. In cases in which this does not occur, detumescence may be encouraged with pharmacologic agents such as phenylephrine (Lue et al., 1986). Anesthesia should be alerted to injection of this vasoactive substance as overly judicious use may lead to systemic cardiovascular changes. Considerable attempts should be made with vasoactive substances, but if these all fail, perineal urethrostomy can be used to gain access in a dire situation.

Postoperative.

Original estimates of **bladder neck contracture** were 2% (Greene and Holcomb, 1979). Subsequent data have shown this to be a fairly consistent 2% (Ahyai et al., 2010), although a large range was found in this study (2% to 21%). This complication is thought to result from overresection of the tissue at the bladder neck paired with injudicious fulguration of this area. Undermining of the trigone may create a flap that then heals as a membrane. Patients with this complication customarily report excellent flow rates in the immediate postoperative period that slowly decrease in the coming weeks, months, or years. This course will be well exaggerated over the usual progression of BPH-type symptoms of a weakening stream. The average interval of development was approximately 6 months from the time of the surgery but have ranged from 3 weeks to 10 years (Greene and Holcomb, 1979). If serial flow rates are available during this time, the results will predictably get worse as the contracture develops. **Prompt office cystoscopy should be performed to verify the diagnosis.** Gentle dilation in the office with sounds or a dilating balloon may be attempted. If dilation does not prevail, then evaluation in the operating room with endoscopic incision may be required. If the bladder opening appears completely obliterated, intravenous administration of methylene blue and use of suprapubic pressure may help identify a jet of blue urine to lead the urologist toward the opening (usually located anteriorly). An open-ended ureteral catheter may be placed into the narrowed opening and guide incision of the constricted ring. Incision may be made with a Collins knife or optical urethrotome until the ring springs open. Incisions are generally made aggressively in the patient with a bladder neck contracture after TURP as the sphincter is still anatomically far away; this is in contrast with anastomotic contractures after radical prostatectomy as these contractures sit very close to the sphincter. Once the band has been opened wide enough to accept the cystoscope, additional resection should be avoided as it may exacerbate the healing reaction and cause a re-stenosis. Intractable bladder neck contractures may require an open VY-plasty to solve the problem.

The incidence of **urethral stricture** after TURP has a large variation in reported incidence. Mayer et al. (2012) found that this occurred in 4.1% of cases in the 34 analyzed RCTs, although the severity and necessary treatments were not outlined. The etiology of urethral stricture is thought to be caused by resectoscope trauma, catheter usage, or bacterial infection in the postoperative period. The surgeon should be careful to select an appropriately sized resectoscope sheath to prevent any unneeded trauma. Interesting data from Emmett et al. (1957)showed that only 62% of men who underwent urethral calibration had a urethral meatus and fossa navicularis of 28 F or greater. **Calibration and gentle dilation of the meatus along with careful visual inspection of the urethra on insertion of the cystoscope may help in preventing trauma that may lead to stricture.** The resectoscope should always be well lubricated. The role of a urethral catheter leading to stricture formation is supported by a comparison of patients with suprapubic versus urethral catheters, wherein the former had a lower incidence of stricture formation (Hammarsten and Lindqvist, 1992).

The internal sphincter predominates as a continence mechanism in men. During the course of a normal resection, this sphincteric mechanism is resected or rendered incompetent. (Rolnick and Arnheim, 1949). Without exception, the surgeon must **preserve the external sphincter mechanism,** or the patient will have total or stress urinary incontinence (SUI). This injury may be caused by errant resection or excessive fulguration around the striated muscle fibers. The verumontanum is an invaluable landmark and should be preserved not only as a landmark during the ongoing resection, but also for any future identification during cystouretheroscopy. Resections that are terminated proximal or adjacent to the verumontanum are unlikely to have a significant injury to the external sphincter. However, the extent of the complex smooth and striated muscle fibers that make up the external sphincter are not always clearly demarcated. The anterior portion of these muscular fibers is the least substantial, and the sphincter lies on a tilt with the dorsal portion being the most proximal and thus most likely to extend into the resection. The poor understanding of the complexities of the external sphincter is most evident when one considers the extent of incision during an external sphincterotomy. This purposeful act often requires considerable depth and length, and highlights our poor understanding of post-TURP incontinence. Nonetheless, caution in overresection of the distal portions of the prostate should be exercised. Even in contemporary studies, this is a continued problem. **The study byAhyai et al.** (2010)**found a 0.6% incidence of**

SUI, with some studies reporting up to 5%. However, this is often a transient issue and rarely requires additional intervention.

Significant hemorrhage in the immediate postoperative period is most often caused by incompletely controlled hemostasis during surgery, and minor hemorrhage requiring minimal irrigation is fairly common with a wide variability in occurrence between practitioners (Mayer et al., 2012). **Some delayed postoperative bleeding is frequently noted around 1 to 4 weeks postoperatively and is frequently accompanied by some sloughed tissue or eschar.** Outside of this period, the likelihood of bleeding decreases as the time from surgery lengthens. Limited bleeding may occur for many weeks after the initial resection, but it is usually limited and transient in nature. This customarily responds to curtailing physical activity and increasing fluid intake.

Postoperative urinary retention after any BOO procedure is a common finding. Variability is different based on surgical technique and procedure type. Prolonged catheterization is generally a result of persistent bleeding or surgeon preference. In major case series, this ranges between 6.5% and 7.1% of cases and does not appear to have changed over time (Mayer et al., 2012).

The **need for retreatment** may arise from one of many reasons. **Incomplete resection (likely at the apex or anteriorly), poor patient selection, diagnostic error, and intraoperative technical errors are all possible causes.** The need for retreatment may be caused by urethral stricture, bladder neck contracture, regrowth of BPH, or residual BPH left at the previous surgery. In the meta-analysis of RCTs, Ahyai et al. (2010) found a rate of 0.5% re-intervention for BPH type symptoms with another 0.1% requiring secondary treatment resulting from other causes (e.g., bladder neck contracture, urethral stricture). The need for surgical revision does appear to increase with increasing gland size, and preoperative retention also is a risk factor (Reich et al., 2008).

Urinary storage symptoms are a common finding after any BOO procedure wherein the urethral epithelium is disrupted. The raw prostatic fossa takes time to re-epithelialize, and the patient will likely frequently experience symptoms of **urgency** or **dysuria** during this time. Although wide ranges of reporting are seen for both urgency (0% to 38%) and dysuria (0% to 22%), the physician can expect an average of 2.2% and 0.8%, respectively (Ahyai et al., 2010).

Ejaculatory problems are a significant concern as the bladder neck is resected as part of the procedure. In the TURP arm of randomized series compared with holmium enucleation, the TURP groups had a new incidence of retrograde ejaculation of 62% and 78% (Briganti et al., 2006; Wilson et al.,

2006).

Multiple large series have reported on the effects of TURP with regard to a **change in erection quality.** In a trial of 644 men, 30% noted an improvement in erections after the procedure, and only 20% noted worsening function. The percentage of men engaging in sexual activity before and after surgery was essentially identical (Muntener et al., 2007). Another series showed that a capsular perforation during surgery had a relative risk of 1.12 in postoperative erectile dysfunction (ED) (Poulakis et al., 2006), and other studies did not find an increase in risk (Jaidane et al., 2010). **In a comparative study of patients undergoing either TURP or transurethral resection of bladder tumor (TURBT), the baseline voiding and erectile function in the TURBT group was statistically far superior. However, after prostate resection, the TURP group displayed significant improvements in almost all International Index of Erectile Function-15 (IIEF-15) subdomains with an impressive improvement in erectile function (improving from 7.18 to 20.74). After TURP, the groups were no longer statistically different with regard to voiding and sexual function** (Jaidane et al., 2010).

Conclusion.

Although most men improved in overall QoL and the important symptom and urodynamic outcomes with M-TURP, the morbidity and adverse events are such that multiple different and generally less invasive treatment options have been developed. Although many of these technologies do not achieve the same efficacy as TURP, they are associated with less risk or fulfill a particular treatment niche.

Bipolar Transurethral Resection of the Prostate

Concept.

Bipolar transurethral resection of the prostate (B-TURP) utilizes a specialized resecting loop that incorporates both the active and the return portions of the circuit on the same electrode. Consequently, the current does not need to run through the patient to a return electrode (in the form of a grounding pad), and current is kept at the site of the resection. This innovation in design has also allowed for the resection to take place in ionic irrigating solution and has eliminated most of the risk for TUR syndrome.

True bipolar systems meet the criteria set by the International Electrosurgical

Commission, which requires both active and return poles to be attached in a single system. Frequently a dual-loop design is used wherein both loops are in close proximity to each other at the end of the cutting electrode. In this design, the electrical energy is able to connect between the loops and supply the resecting energy there. Another form of bipolar technology is the PlasmaKinetic (PK) system (Olympus, Tokyo, Japan) wherein energy is initially transmitted from the loop into the surrounding saline. This B-TURP technology is commonly used in the United States, and the mechanism is described in detail here. The saline is vaporized into gas around the loop with additional energy from the loop then converting the gas to plasma. The excited sodium ions of the plasma give this technology the characteristic orange glow. Once created, the plasma molecules are now able to be excited for use in resection. Although this seems like a dynamic and explosive process, it actually allows tissue resection at lower temperatures with a lower voltage. In practice, this allows for a more simultaneous cutting of tissue with sealing of vessels leading to the overall improved hemostasis recognized in studies.

Although the PK loop and scope look almost identical to the conventional monopolar systems, the loop is made of platinum-iridium instead of the standard tungsten loop. This specialized loop is able to withstand the electrical and thermal stresses that come with plasma usage (Issa, 2008).

When using the coagulation setting in this system, a different process takes place. Plasma is not created, and the input energy from the generator is used to increase the tissue temperature and seals the vessels in the prostate. The depth of energy transmission is not as important as previously seen with the monopolar system. Additionally, the lower voltage and temperature used in a plasma system minimizes tissue charring and may lead to a decrease in unnecessary tissue coagulation and a subsequent decrease in storage symptoms.

Technique.

B-TURP has an almost identical technique to the M-TURP with regard to approach to the resection. However, the resectionist may note that the bipolar technology allows for quicker resections as bleeding vessels are less likely to be encountered as the simultaneous cutting and sealing of vessels decreases time spent controlling hemorrhagic areas. The previous generator with the PK system would often have trouble overcoming the additional energy needed to ignite the plasma. The newer SuperPulse generator has increased capacity and has made this less of an issue. However, the resectionist may still note a drag on the loop as it first comes in contact with the tissue.

Outcomes

Single-Cohort Studies.

With the B-TURP's similarity to its monopolar predecessor, comparative trials quickly arose. Compared with other treatment systems, relatively few single-cohort studies of bipolar TURP are available in the literature. One of the large early studies reported excellent results with the PK system (Falsaperla et al., 2007). With a relatively short mean catheterization time of 1.3 days, the authors found a mean increase in Qmax of 190% at 12 months from the procedure. The AUA-SS decreased by an average of 79%. Complications were relatively infrequent, with acute urinary retention, urethral strictures, bladder neck contracture, and urinary incontinence recorded in only 1.57%, 2.57%, 1.28%, and 0.77% of patients, respectively. A smaller study published around the same time had equally impressive results and included a high percentage (49%) of patients who had urinary retention (Ho et al., 2006). Patients had improvements in mean Qmax (6.5 to 18.3 mL/sec) and AUA-SS (22.6 to 6.5) at 1 year. Plateaus in these improvements were noted at around 3 months.

Comparative Studies.

In the excellent review of the bipolar technology by Issa, a 10-year Medline review of outcomes of both M-TURP and B-TURP was conducted for the years 1997 to 2007 (Issa, 2008). **He found similar efficacy in regard to AUA-SS, QoL score, Qmax, and residual urine.** Multiple comparisons of bipolar and monopolar technology have been published by a European consortium (Mamoulakis et al., 2012). Utilizing the Autocon II 400 ESU system (Karl Storz, Tuttlingen, Germany), they were able to conduct an RCT comparing monopolar versus bipolar techniques. This generator has a touch-screen system that allows for selection of either a monopolar or bipolar current. Although the study states it is double-blind, they report that surgeons could not be blinded at procedure, and only the assessors were blinded to treatment selected. Additionally, resection technique, power settings, irrigant, and anesthesia type were not standardized across treatment centers. **Improvements were pronounced in both groups, with no difference in voiding outcomes at 6 weeks. The only significant difference over the short follow-up in this study was the decrease in serum sodium, although there was no statistical difference in occurrence of TUR**

syndrome, mostly because of the low incidence of the event overall. Widespread application of these findings may be difficult as this is a rarely used platform, and this is the only RCT utilizing this technology.

In the more commonly studied PlasmaKinetic technology, Patankar et al. (2006) reported that at 3-week follow-up robust changes in AUA-SS and Qmax were noted in both groups with no statistical difference. Differences in blood loss and time with catheter favored the bipolar group, with postoperative complications like hematuria, clot retention, and blood transfusion appearing to be more common in M-TURP patients.

A meta-analysis of RCTs found similar results with no difference in regard to AUA-SS, QoL score, Qmax, or change in PVR (Ahyai et al., 2010)**, and another meta-analysis of RCTs looking at flow rates at 12 months found a slight (0.72 mL/sec) weighted mean increase in flow rates for B-TURP** (Mamoulakis et al., 2009). This finding is not clinically significant and was mostly bolstered by the large difference in a highly weighted study.

Omar et al. (2014) published a large meta-analysis and systematic review in which they examined 949 abstracts and found 24 trials acceptable for inclusion in the review. **No statistically significant differences were found in terms of AUA-SS or QoL score between groups. The analysis of Qmax revealed improvements that were more significant in the bipolar group at 3, 6, and 12 months but were once again skewed by a few largely weighted studies.** The meta-analysis could not show homogeneity among studies, and the result was not clinically significant. **A second meta-analysis evaluating outcomes only at 12 months found that bipolar devices demonstrated no significant difference in AUA-SS or prostate volume reductions compared with M-TURP. However, B-TURP seemed associated with a better Qmax and a lower PVR** (Cornu et al., 2015).

Complications.

Issa (2008) also reviewed complications from 1997 to 2007. **The overall rate of adverse events was lower with B-TURP (15.5% vs. 28.6%, $P < .001$) compared with M-TURP**. This was mostly fueled by lower rates of bleeding, transfusion, time with catheter, CBI need, hyponatremia, and TUR syndrome differences. Although the overall rates of complications were statistically significant, these individual subgroups consistently favored bipolar TURP with only occasional statistical significance.

Intraoperative and Perioperative.

Although the most exciting innovation with the bipolar technology is the **ability to perform the resection in an ionic iso-osmolar solution,** other possible improvements in outcomes may be related to this advancement in technology. A well-recognized complication of the M-TURP is the bleeding risk, which may lead to repeat irrigations and prolonged catheterization. The energy profile of the bipolar system has a “cut and seal” effect on vessels that should improve hemostasis and lead to decreased bleeding complications and transfusion rates (Issa, 2008).

In the meta-analysis of patients undergoing bipolar TURP, no patient suffered from **TUR syndrome. The authors concluded that by treating 50 patients with B-TURP, one case of TUR syndrome could be prevented** (Mamoulakis et al., 2009).

The hemostasis achieved during bipolar resection has allowed for reductions in many bleeding measures. A relative risk of 0.53 for **blood transfusion** and 0.48 for **clot retention** with bipolar resection was found compared with monopolar resection, with 2.3% and 2.7% of patients having these complications, respectively, in the bipolar cohort (Omar et al., 2014). The improved hemostasis and absent risk for TUR syndrome allows the urologist a longer resection time and the ability to treat larger glands. Improved visualization may also lead to a decrease in **capsular perforations** and **operative time** (Erturhan et al., 2007). Bipolar resection is also associated with a decrease in overall immediate reoperation rate (OR = 0.43) (Cornu et al., 2015).

Postoperative.

There are many different types of bipolar systems, all utilizing different mechanisms. The TURis systems (Olympus, Tokyo, Japan) were originally mistakenly labeled as bipolar systems (Issa, 2008). In reality, the return electrode in these systems was the outer resectoscope sheath. This could potentially predispose the patient's entire urethra and penis to the return energy. Ho et al. (2006) reported a 6.3% **urethral stricture** rate during procedures utilizing the TURis system. The review by Issa (2008) found an overall risk for urethral stricture of 4.7%, which was higher than the TURP group (2.7%, P = NS), and other authors did not find this difference (Michielsen and Coomans, 2010). The meta-analysis from Cornu et al. (2014) found that there was no difference between M-TURP and B-TURP for the incidence of urethral stricture or **SUI.**

Other late complications like **bladder neck contracture** and need for

retreatment of BPH do not appear to be much different from those found with conventional M-TURP (Ahyai et al., 2010). Overall reoperation rates at 1 year were low in both M-TURP and B-TURP groups and were not statistically different (Cornu et al., 2015).

Again, the improved hemostatic properties of the bipolar technology were evident during postoperative care as patients were more likely to have reduced **catheter and hospital times** (de Sio et al., 2006; Singh et al., 2005).

Conclusion.

Results for the bipolar resection system are encouraging, and this technology will likely replace M-TURP as the gold standard for treatment of BPH in the coming years. Although clinical outcomes are roughly equivalent, the improved hemostasis of the procedure and use of isotonic irrigating solution allows for longer and safer resections. Although different systems utilize different approaches to meet the bipolar standards, finding differences among systems with regard to outcomes is challenging at this point.

Prostatic Urethral Lift

Introduction.

The prostatic urethral lift (PUL), marketed under the name UroLift (NeoTract, Inc., Pleasanton, CA), was developed in 2004 as a treatment option for BPH that works by **altering prostatic anatomy without ablating tissue. These permanent transprostatic implants take the form of sutures that are delivered by a handheld device through a cystoscope to mechanically open the prostatic urethra by compressing the prostate parenchyma** (Fig. 146.5). The sutures have “T-shaped” bars on the ends of the suture and are spring-loaded and placed so that the bars are set with one outside the prostate and the other within the prostatic urethra lumen. The suture is placed on tension and once activated pulls the lumen of the prostatic urethra toward the capsule, opening the prostatic urethral lumen. The PUL is used to treat the lateral lobes of the prostate and is thus not appropriate for patients with a median lobe. Roehrborn et al. (2013) demonstrated with cystoscopy that the implant does not encrust, and epithelializes within 12 months. Histopathologic analysis of tissue obtained after PUL demonstrates a benign response to the implant (Woo et al., 2011) and no changes in PSA (Woo et al., 2012).

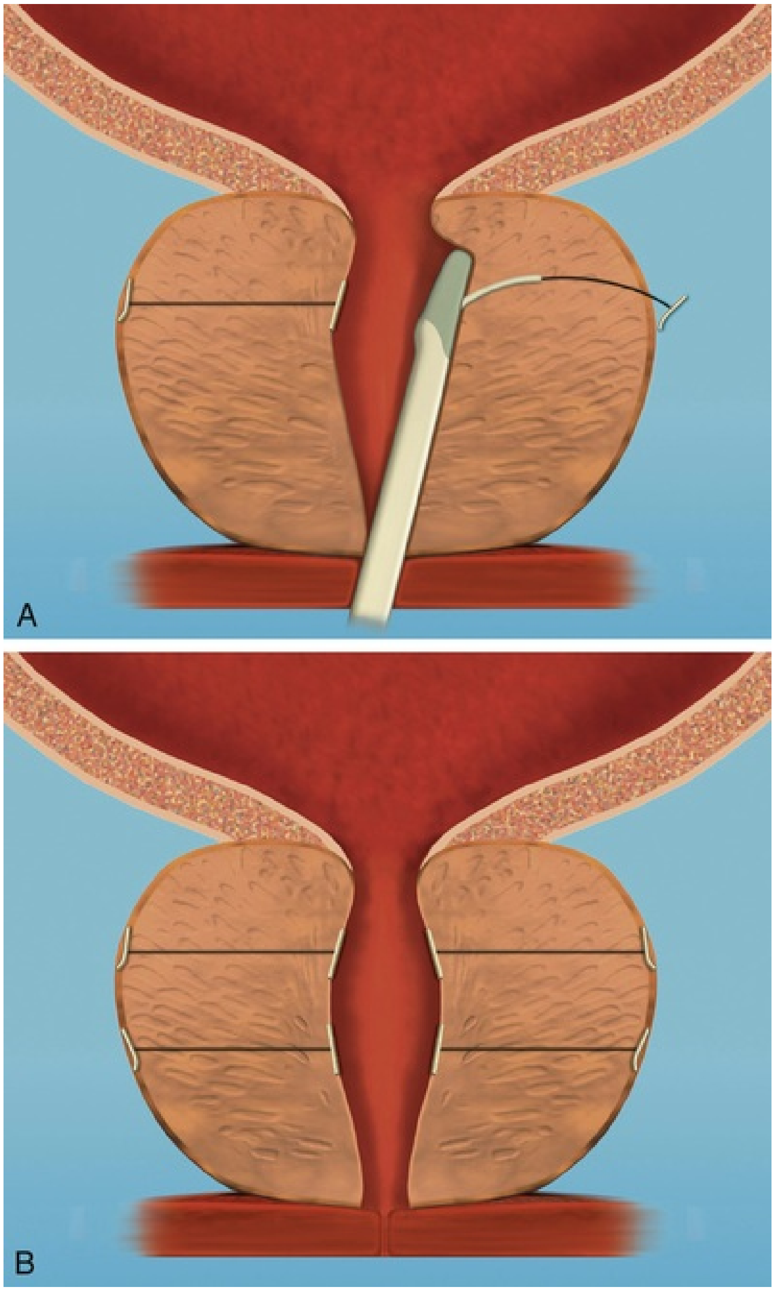

FIG. 146.5 (A and B) Placement of Urolift devices. (Courtesy of NeoTract, Inc.)

The particular advantages of this technology include low rates of local symptoms along with minimization of impact on sexual factors like ED and ejaculatory problems. As the procedure is nonablative and the urethral mucosa largely stays intact, there should be a minimization of dysuria and other storage symptoms along with more severe complications like bladder neck contracture and postoperative incontinence. Roehrborn et al. (2016) reported that the majority of adverse events were transient, mild to moderate in severity, and occurred primarily in the immediate postoperative period. As the implants are placed anterolaterally in the prostate, injury to the neurovascular bundles or dorsal venous complex should not occur (Fig. 146.6). Preservation of the bladder neck maintains ejaculatory function, making it an option for men desiring a minimally invasive treatment that will not affect sexual function. Verifying the absence of an obstructing middle lobe or median bar is mandatory for the use of PUL as is the need to restrict treatment to those prostates less than 80 g. Because of these size restrictions, the clinician should verify the absence of the middle lobe with either cystoscopy or prostate ultrasonography before committing the patient to this procedure. Similarly, the requirement of verifying the proper prostate volume can be accomplished by cystoscopy, TRUS, or abdominal ultrasonography as detailed earlier.

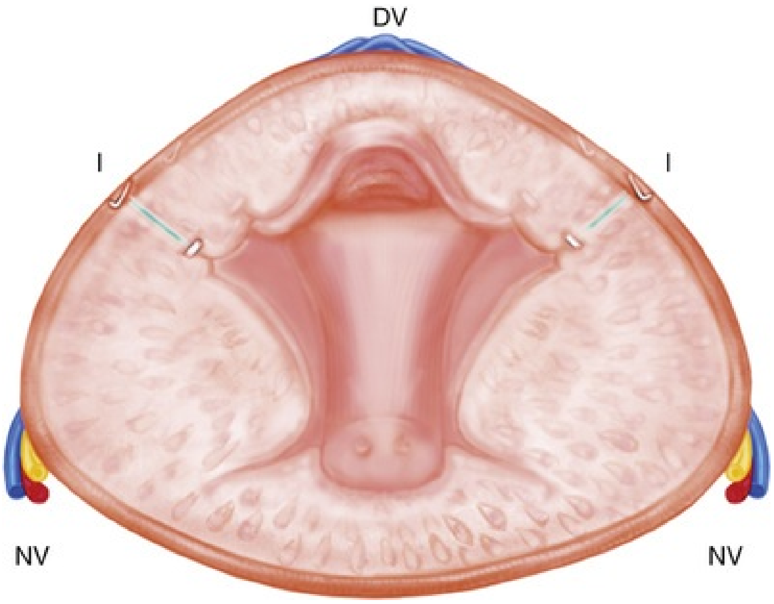

FIG. 146.6 Placement of implants *(I)* in the anterolateral position in the prostate between the dorsal veins *(DV)* and neurovascular bundles *(NV).* (Courtesy NeoTract, Inc.)

The procedure is done through a rigid cystoscope sheath and can generally be performed in the office setting with only local anesthesia. Overall, the procedure is well tolerated with minor and self-limited postoperative adverse events.

Outcomes

Single-Cohort Studies.

Following a proof-of-concept clinical study (Woo et al., 2011), a multicenter study of 64 subjects at five Australian sites led to approval with European and Australian regulatory bodies (Chin et al., 2012, Woo et al., 2012). This was followed by a prospective RCT of 206 men, 140 in the PUL arm and 66 in the sham arm, which is also known as the Luminal Improvement Following Prostatic Tissue Approximation for the Treatment of LUTS secondary to BPH (LIFT) study (Roehrborn et al., 2013). Subjects were unblinded at 3 months, with 80% of the subjects in the sham group enrolling in a crossover study (Cantwell et al., 2014; Rukstalis et al., 2016). The mean procedure time was 66 minutes, and in the North American arm 99% of the procedures were completed under local anesthesia. Patients in the PUL arm experienced an improvement in AUA-SS from 22 at baseline to 11.5 at 12 months ($P < .0001$) (Roehrborn et al., 2013) and 14.47 at 60 months ($P < .0001$) (Roehrborn et al., 2017). Maximum flow rate in the PUL arm improved by 4.0 mL/sec at 12 months ($P < .0001$) and 3.21 mL/sec at 60 months ($P < 0.0001$) when compared with baseline (Roehrborn et al., 2013, 2017).

Comparative Studies.

Gratzke et al. (2017) recently published a prospective, randomized, controlled, nonblinded study of 80 patients who underwent PUL or TURP. Inclusion criteria included men with an AUA-SS greater than 12, Qmax less than or equal to 15 mL/sec, and prostate volume less than or equal to 60 g. TURP was superior to PUL in terms of improving IPSS and Qmax at 1 and 2 years. Retreatment rates were 13.6% for the PUL and 5.7% for the TURP arms at 2 years. This study had many limitations, including: (1) an unclear risk for bias for many reported domains, (2) imprecise outcome measures with wide confidence intervals, and (3) sparse data in many areas. In this comparison of TURP versus PUL, the evidence revealed that there was a lower proportion of individuals in the PUL group who responded to treatment at long-term follow up (>12 months) as measured by the IPSS reduction goal of greater than or equal to 30%. Additionally, the % responders based on the IPSS had a relative effect (95% CI) RR of 0.81 (0.65 to 1.00) (PUL vs. TURP), an anticipated absolute effects (95% CI) of 73.4% (58.9 to 90.6) for PUL and 90.6% for TURP, or a difference of 17.2% fewer for PUL versus TURP (31.7 fewer to 0 fewer). Similarly, when comparing the mean change in IPSS, it was noted that the mean difference between PUL and TURP was 6.1 points lower for PUL (2.2 higher to 10 higher), supporting the notion that the long-term improvement in overall IPSS scores was greater with TURP compared with PUL. Although PUL is clearly a MIST, the comparable impact on IPSS QoL was not different from TURP as the mean change in IPSS-QoL from baseline through long-term follow up (>12 months) was similar with PUL compared with TURP. Importantly, it was noted that the need for reoperation was 13.7% (2.9 to 63.4) for PUL and only 5.7% for TURP (RR 2.4 [0.5 to 11.1]).

Erectile function was preserved in both arms as assessed by SHIM, and ejaculatory function was superior for the PUL group, with 100% of patients in the PUL group reporting preserved function compared with only 34% in the TURP group at 2 years.

One of the purported advantages of PUL includes the preservation of sexual function. McVary et al. (2014a) demonstrated that the sexual function of men with normal or moderate ED at baseline was unaffected, and those with severe ED actually reported modest improvement. **There was no evidence of de novo ejaculatory dysfunction or ED over the course of the study.** Ejaculatory bother improved by 40% at 1 year ($P < .001$), and intensity of ejaculation and amount of ejaculate improved by 23% and 22%, respectively ($P < .001$). This larger studied verified the findings previously published in initial testing (Woo et al., 2012).

Overall, patients must be warned that PUL is a relatively new intervention for LUTS/BPH, thus the long-term durability is uncertain, though long-term uncontrolled data are available. Durability was reported in the most recent 5-year data (Roehrborn et al., 2017). Surgical retreatment rates for PUL are concerning as noted in Roerborn et al., 2017. These retreatment rates were 5% at year 1, 10.7% at year 3, 13.6% at year 4, and 13.6% at year 5. When closely evaluating the original 140 participants randomized to PUL were followed for 5 years. Results showed PUL demonstrated modest durability. This modest durability is different from that concluded in the original article concerning 5-year data, as on closer inspection 6 patients received a second PUL procedure, 13 went on to a TURP procedure or its laser equivalent, 15 went on to BPH/LUTS medical therapy, and 13 had PUL implants removed (primarily for encrustation). Thus the retreatment rate, additional procedure rate, and need for return to medication combine to an overall “failure” of approximately 33.6%. (Roehrborn et al., 2017).

Complications.

A meta-analysis by Perera et al. (2015) demonstrated that procedure-related adverse events were more common in the PUL group, with the most common being dysuria (25% to 53%), hematuria (16% to 75%), and pelvic pain (3.7% to 19.3%). There were no reports of bleeding requiring transfusion, or new-onset SUI. One-third of PUL subjects (32%) required catheterization for failed voiding trial for an average catheter time of 0.9 day. During the LIFT study, 2% of implants were suboptimally placed and had to be removed because of exposure of the stainless steel urethral endpiece (Roerhborn et al., 2017).

Conclusion.

The utility of PUL depends on whether it is being evaluated as a substitute for medical or surgical therapy. It is not suited for men with a gland larger than 80 g as the LIFT study excluded men with a gland larger than 80 g. **PUL is contraindicated in men with a median lobe, which is why providers should perform cystoscopy before evaluating urethral anatomy.** It does offer advantages over currently available minimally invasive surgical options for the treatment of BPH, namely preservation of sexual function. Despite 5-year data supporting its modest durability, younger men should be counseled about the likelihood that they will require surgical treatment in the future with progression of their BPH. PUL may, however, be well suited for men who are unwilling to submit to daily medical therapy.

Convective Radiofrequency Water Vapor Thermal Therapy

Introduction.

Convective radiofrequency (RF) water vapor thermal therapy, marketed as Rezūm (NxThera, Inc., Maple Grove, MN), utilizes *convective* rather than *conductive* energy to ablate prostatic tissue. Rezūm utilizes RF power to generate thermal therapy in the form of water vapor, which is injected transurethrally into the transition zone of the prostate. The water vapor is injected at 103°C for 9 seconds at a pressure slightly above interstitial pressure, facilitating the dispersion of water vapor through the cellular interstices via convective energy. As the water vapor comes into contact with prostatic tissue, it condenses from steam to a liquid, releasing 540 calories of energy per gram onto the exterior cell membrane of the tissue, which causes cell death and tissue necrosis in a spherical ablative lesion of 1.5 to 2.0 cm, which has been confirmed by MRI and pathologic studies (Bhowmick et al., 2004, Dixon et al., 2015a,b; Hahn and Özişik, 2012, Mynderse et al., 2015).

Unlike *conductive* energy, which is used in transurethral needle ablation (TUNA) and transurethral microwave thermotherapy (TUMT), *convective* energy requires the application of lower energy levels for a shorter duration to induce tissue necrosis (Bhowmick et al., 2004). Water vapor therapy only uses 4 kJ per procedure to produce cell necrosis compared with TUNA (20 kJ), TUMT (86 kJ), and other laser ablative technologies (250 kJ). An additional advantage of water vapor therapy over other minimally invasive technologies include its ability to respect the natural collagen barriers that compartmentalize the prostate, limiting its effect to the hyperplastic tissue of the transitional zone and precluding thermal effects outside of the desired treatment area. Lastly, water vapor therapy preserves ejaculatory function, unlike transurethral vaporization of the prostate (TUVP) and TURP.

Technique.

The Rezūm system is composed of a generator with a handheld delivery device that includes a transurethral rigid cystoscope and an 18-gauge retractable needle with 12 vapor-emitting holes located at the tip of the delivery device (Fig. 146.7). It utilizes saline irrigation solution to enhance visualization and cool the surface of the urethra. The vapor needle penetrates the prostate at a fixed length of 10.25 mm and is deployed at the 3 o'clock and 9 o'clock positions starting 1 cm distal to the bladder neck, leaving approximately 1 cm between injection sites to create contiguous overlapping thermal lesions distally until the proximal edge of the verumontanum (Fig. 146.8). The procedure can also be modified for patients with a median lobe, giving it an advantage over other minimally invasive procedures. It was developed as a minimally invasive procedure intended for the outpatient setting. Water vapor thermal therapy can be performed with oral sedation, conscious sedation, or a regional prostate block.

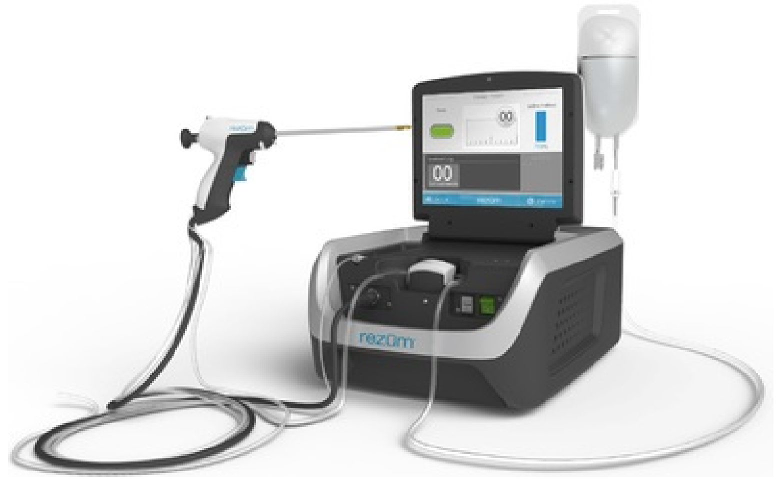

FIG. 146.7 Convective water vapor ablation is a transurethral radiofrequency thermal therapy used to treat LUTS/BPH using a handheld device and a central generator unit (Rezūm system). The Rezūm system delivers radiofrequency-generated thermal therapy in the form of water vapor, directly to the extra prostate tissue.

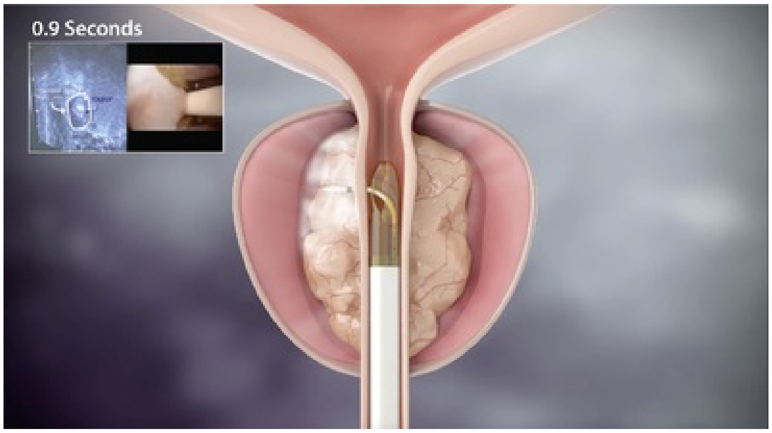

FIG. 146.8 *Inset (left),* The treated prostate using the convective water vapor device with the vapor delivery needle deployed in sequence. *Inset (right),* Transurethral delivery using a vapor delivery needle shown within the transition zone. Water vapor is delivered in a predetermined amount in 9 seconds. (Courtesy of NxThera, Inc.)

Outcomes

Single-Cohort Studies.

In the first-in-man study reported by Dixon et al. (2015a), researchers analyzed histopathologic specimens of 7 patients treated with water vapor thermal therapy followed by suprapubic prostatectomy. Tissue staining of the extirpated adenomas demonstrated nonviable tissue from the steam injection, thrombosed vasculature, and general preservation of the prostatic urethral epithelium. The excised tissue did not show carbonization or heat fixation effects, and no thermal effects were observed outside of the prostate. A second cohort of 15 patients underwent water vapor thermal therapy followed by gadolinium-enhanced MRI 1 week after surgery. MRI confirmed treatment defects in the transition zone, with the largest defect volume of 35.1 cm^3 and no thermal effects observed in the peripheral zone.

A subsequent prospective, nonrandomized single-arm pilot study of 65 patients by Dixon et al. (2015b) demonstrated the safety and efficacy of water vapor thermal therapy in men with moderate to severe LUTS. Patients were evaluated at 1 week, 1 month, 3 months, 6 months, and 12 months post-treatment. The mean baseline was IPSS 21.6, QoL score 4.3, Qmax 7.9 mL/sec, and PVR 92.4 mL. Subjects demonstrated a sustained statistically significant improvement in IPSS, Qmax, and QoL at all time points out to 12 months. A total of 36 patients were catheterized immediately after the procedure or before discharge, with an average catheterization time of 5.6 days. An additional 11 patients were catheterized after release for an average catheter time of 4.3 days. IIEF scores did not change significantly from 1 to 12 months, and although PSA level initially increased at 1 week and 1 month, PSA returned to baseline values by 3 months. A total of 125 AEs were reported by 45 patients, the most common being urinary retention (33.8%), dysuria (21.5%), urinary urgency (20%), UTI (20%), hematuria (13.8%), and poor stream (13.8%).

Comparative Studies.

The largest reported study to date includes a randomized controlled trial of 197 men who underwent either water vapor thermal therapy (136 subjects) or sham procedure (61 subjects), with 53 patients from the sham group crossing over to the treatment group after 3 months. Inclusion criteria included prostate volume less than 80 g and PVR less than 250 mL; men who had urinary retention were excluded. The most recent 2-year data confirmed long-term efficacy with a 51% reduction in IPSS, 4.2 mL/sec improvement in Qmax, and 50% improvement in QoL at 24 months (Roehrborn et al., 2017). Patients who underwent treatment of a median lobe showed similar improvement in IPSS and Qmax as those without a median lobe who underwent water vapor therapy (McVary et al., 2016a). Although there were initial changes in PSA (fivefold increase at 1 week), PSA returned to baseline by 3 months (Mynderse et al., 2015).

Sexual function was assessed using IIEF and Male Sexual Health Questionnaire-Ejaculatory Dysfunction (MSHQ-EjD) scores. No changes were noted in the treatment group at 3 months, and ejaculatory bother improved by 31% at 12 and 24 months (McVary et al., 2016b; Roehrborn et al., 2017). No de novo ED was reported in the treatment group, although six (4.4%) men reported decreased ejaculatory volume, and four men (2.9%) reported anejaculation. Authors stipulated that this may have occurred if the initial treatment was delivered too proximal to the bladder neck. For all subjects, the retreatment rate was 3.7% at 24 months (Roehrborn et al., 2017).

Complications.

The majority of patients who underwent treatment with water vapor thermal therapy did not report any adverse events. Of those patients who did report an adverse event, events were typically mild to moderate in severity and resolved within 3 weeks. Of the 189 subjects who underwent water vapor thermal therapy, four patients experienced a procedure-related serious adverse event, one developed de novo extended urinary retention, one experienced a bladder neck contracture and bladder stone at 6 months, one developed urosepsis after cystoscopy performed in the follow-up period, and one developed nausea and vomiting caused by alprazolam requiring overnight hospitalization for observation. The most common nonserious procedure-related adverse events included dysuria, hematuria, urinary frequency and urgency, hematospermia, and urinary tract infection (McVary et al 2016a; Roehrborn et al., 2017).

Conclusion.

Convective water thermal therapy ablation of the prostate for the treatment of LUTS/BPH utilizes new technology to provide durable efficacy evident at 2 years of follow-up. It offers the ability to target hyperplastic prostatic tissue within the transition zone, while avoiding delivery of high energy outside of the desired treatment area. Patients will benefit from improvement in clinical symptoms as measured by IIEF, Qmax, and QoL scores, including patients with a median lobe. Water vapor thermal therapy should be used cautiously in patients with a gland greater than 80 g and in men who have urinary retention. **Water vapor thermal ablation therapy boasts a favorable safety profile and a low retreatment rate, and it can be used in the office or outpatient setting using minimal anesthesia, making it an attractive option for both providers and**

patients, particularly those concerned with preserving sexual function.

Key Points

- PUL is an option for patients with LUTS/BPH provided prostate volume is less than 80 g and the clinician has verified the absence of a middle lobe.
- Patients electing PUL or water vapor thermal ablation therapy should be warned that long-term durability is uncertain, though long-term uncontrolled data are available.
- In appropriate patients, PUL and water vapor thermal ablation therapy are less likely to affect erection and ejaculation than conventional therapies.

Transurethral Vaporization of the Prostate

Introduction and Concept.

Prostate vaporization was first reported by Kaplan and Te in 1995 and is contemporary with many of the other MISTs in this regard. **However, this technique used the same set of equipment as TURP at that time with the exchange of the resecting loop for an element with a larger surface area.** Strategically, these modifications allowed for a broader contact area over which the current was delivered to the prostate tissue and did not involve tissue resection. These changes allowed for the use of a higher energy that led to controlled tissue vaporization with simultaneous underlying tissue coagulation and ideally improved hemostasis during treatment. **These modifications to the conventional TURP provided the urologist with an improved visual field in which to work and did not require the capital involved with the purchase of new equipment seen with other TURP alternatives at that time.**

The power distribution along the electrode provides the advantages of TUVP. As the leading edge of the electrode makes first contact with the virgin tissue (low electrical resistance), a high volume of energy is delivered, and tissue vaporization occurs. The lagging edge of the electrode interacts with tissue that has already been desiccated to some degree giving it a higher resistance to the supplied energy. Overall, this leads to a combination of tissue vaporization at the leading edge with the lagging portion of the electrode then providing almost instantaneous tissue coagulation. This was verified by a two-staged in vivo study wherein the cutting current was found to cause vaporization with minimal tissue necrosis. When the obtained TURP samples were excised using coagulating current, coagulative necrosis predominated in samples (Juma, 1996).

A variety of different electrodes were used initially, including the VaporTrode (Fig. 146.9), formerly ACMI, now part of Olympus), which is a grooved roller electrode and is the most studied of the monopolar options. Additional options included a fluted and spiked variety (Figs. 146.10 and 146.11) Each of these options provided an irregular edge for tissue contact wherein electrical charge would accumulate (Narayan et al., 1996). Although all were conceptually different working elements, these were easily fitted to existing equipment with fairly similar results.

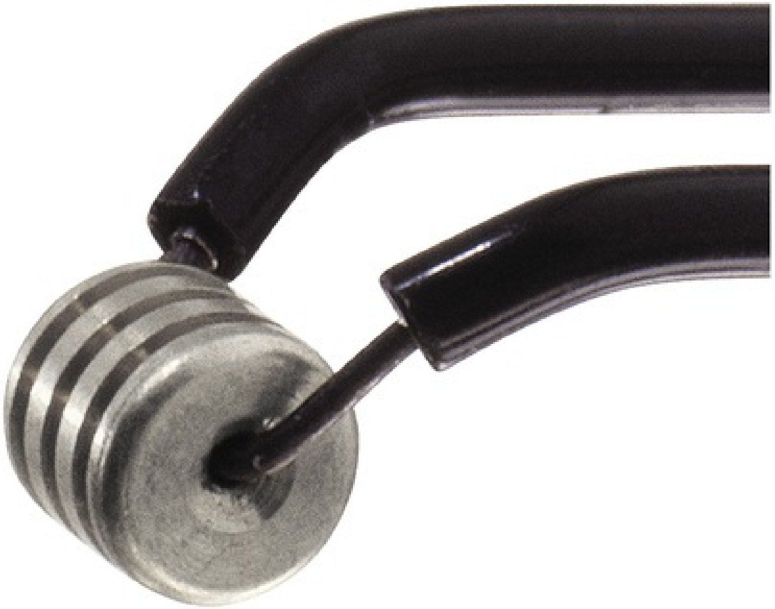

FIG. 146.10 Fluted electrode. (Courtesy of Olympus, Inc.)

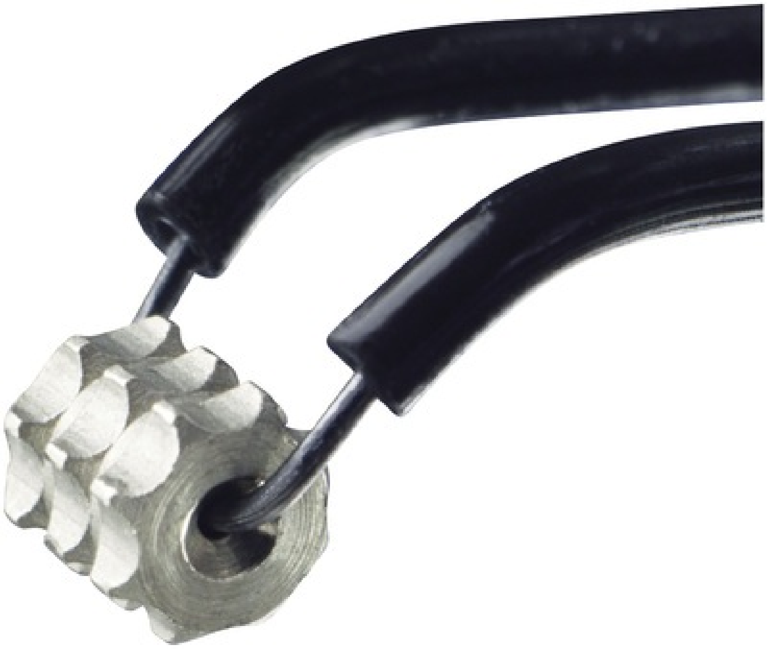

FIG. 146.11 Spiked electrode. (Courtesy of Olympus, Inc.)

The technology was updated in the late 1990s and is now customarily done with bipolar current allowing the use of isosmotic solution as irrigant. The use of bipolar current concentrated the current at the end of the instrument as described in the Bipolar Transurethral Resection of the Prostate section earlier in this chapter. Initial bipolar vaporizations were done with the Gyrus Axipolaire (now part of Olympus), a nonrotating element composed of an 80/20 platinum/iridium alloy that was separated from the stainless-steel return electrode by a ceramic insulator. This operated by forming a vapor pocket at the tip of the device that had a high temperature. When this pocket was brought into contact with the prostate, tissue vaporization would occur, but the electrical circuit would be completed with the low-impedance saline allowing the active electrode to arc to the return electrode. Current was not required to pass through the patient, and deeper tissue heating would not occur.

Currently, Olympus markets the updated variation of the bipolar technology that utilizes PlasmaKinetic technology. The PlasmaButton electrode (Fig. 146.12) utilizes a half-spherical shape that provides a large surface area for current accumulation. Plasma is generated in a similar fashion to that described in the Bipolar Transurethral Resection of the Prostate section. However, because of the large surface area of the working element, tissue contact is almost always required to create the orange “corona.”

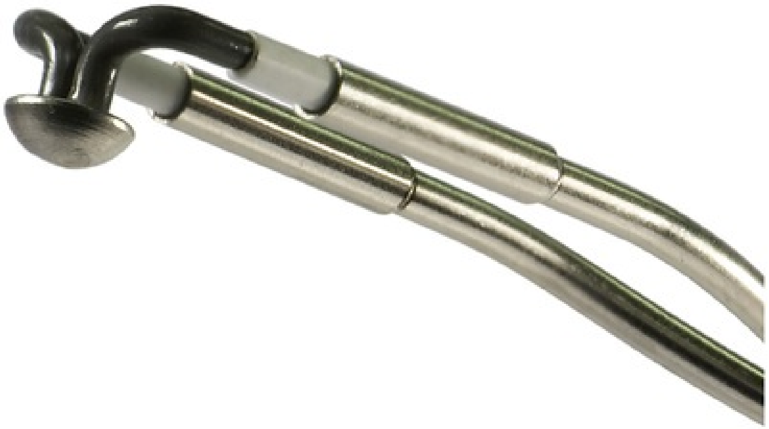

FIG. 146.12 PlasmaButton electrode. (Courtesy of Olympus, Inc.)

Unlike other TURP alternatives, general or regional anesthesia is generally required. As all tissue is vaporized, no pathologic specimen is available for examination.

Technique

Preoperative.

The procedure is generally done under general or regional anesthesia. Once this has been established, the patient should be carefully placed into the dorsal lithotomy position with all pressure points carefully padded. Adequate antibiotic coverage should be given and a standard skin preparation should be used. A grounding pad will be required for a monopolar approach but is unnecessary if a bipolar technology is used. Appropriate irrigating fluid should be maintained at body temperature and placed at a height that allows adequate visualization without compromising patient safety.

Intraoperative.

As described byKaplan and Te (1995)**, the operative technique is similar to a standard TURP. Standard transurethral resection equipment is used.** The major difference is the use of a specially designed electrode for vaporization and replaces the standard loop TURP electrode. This technique was originally described with the VaporTrode and required a non-ionic solution as it was a monopolar technology. The VaporTrode is a spherical electrode on a transverse-oriented axis that will roll as it is drawn along tissue. This allows continuous contact with tissue. The Olympus PlasmaButton electrode has replaced this in many urologists' armamentarium as this technology allows the procedure to be done with normal saline irrigation. The PlasmaButton electrode has a half-moon shape that provides a large surface area for contact with tissue without the moving parts of the VaporTrode.

As always, the scope and moving pieces should be examined and checked before being placed into use. An obturator is usually used to place the resectoscope sheath. The bladder should once again be examined for any pathology before beginning; the location of the ureteral orifices and verumontanum should also be identified.

Although alternate strategies certainly exist, the initial technique will be described here. **The "cutting" current is used for vaporization with the "fulguration" current leading to tissue coagulation.** Common monopolar power settings are 200 W to 240 W for cutting current and 60 W for coagulation. The bipolar technology uses settings of 280 W and 140 W.

In this technique, the surgeon begins by vaporizing the middle lobe from the bladder neck to the verumontanum (between the 5 o'clock and 7 o'clock positions). This will open a large channel for fluid irrigation and continued visualization. The vaporization is accomplished with overlapping sweeps of the electrode that can simultaneously deepen and widen the channel. The depth of the treatment remains the same as visualization of the white fibers of the surgical capsule marking the desired depth of vaporization.

Once a sufficient channel has been opened for irrigation flow, the lateral lobes are then vaporized starting at the 1 o'clock position to the 5 o'clock position moving in a clockwise fashion. The urologist should encounter minimal bleeding with this technique with any hemorrhagic area controlled at the time of identification. Similar to the TURP loop, the electrode can be used to place pressure on the bleeding area with “spot treatment” using the coagulation setting. The coagulation setting utilizes a lower energy setting and will coagulate tissue with minimal further vaporization.

After the left lobe is completed, the right lobe may be vaporized starting at the 11 o'clock position and moving counterclockwise down to the 7 o'clock position. This will complete all but the anterior area of the vaporization. The volume of irrigant in the bladder will often change the surgeon's perspective on the magnitude of the cavity in the prostatic fossa as a full bladder will naturally pull the prostatic fossa open. When vaporizing the anterior portions of the prostate, one may find that this is easier with a bladder at a lower overall volume as the anterior aspects fall into the surgeon's view.

Vaporization of tissue around the prostatic apex can be a problem during the procedure with concerns of energy advancing beyond visualization leading to sphincteric injury. The risk for sphincteric injury must be balanced against the risk for symptom recurrence with avoidance of sphincteric injury being paramount. Because of these difficulties and fear of unrecognized vaporization depth, one group described a hybrid technique of resection of apex tissue with fulguration of the resected bed afterward. Although economically less sound because of the use of two electrodes, this is a possible approach (Tefekli et al., 2005).

Once hemostasis has been achieved, the scope can be removed and a Foley catheter is placed. The catheter should be irrigated, and the return of clear to light pink irrigation fluid should be confirmed before terminating the procedure.

Postoperative.

Patients can expect the catheter to be removed within the first 24 hours, and we commonly remove this the morning of the day after surgery as long as there is minimal bleeding and no unforeseen intraoperative complication. Patients should be able to void shortly thereafter. Some authors have performed the procedure as a same-day discharge procedure because of the improved hemostasis (Eaton and Francis, 2002). Convalescence should be fairly rapid, but trauma or pressure to the perineum should be avoided with similar instructions as for patients undergoing TURP. An eschar or other solid tissue mass may be passed around 7 to 14 days after the operation.

Outcomes.

Outcomes for both monopolar and bipolar studies will be presented in the following sections and marked accordingly. **Overall, initial results of monopolar TUVP were similar to those for TURP with a decrease in some adverse events. Long-term durability came into question, and enthusiasm for TUVP waned in the late 1990s to early 2000s. The update to bipolar technology renewed some interest in the technique, and although long-term durability is untested, it is a promising improvement.** However, in almost all studies, maximum prostate volume is limited to 70 to 80 g, making application of the technology to large glands unknown.

Animal/In Vitro Studies.

In a canine model, Perlmutter et al. (1995) examined the grooved rolling cylinder (Richard Wolf Medical, Vernon Hills, IL) and provided some basic understanding of coagulation depth and peripheral heating. They found that multiple passes in the same area did increase the depth of the coagulated zone (78% deeper than a single pass). Temperatures at the neurovascular bundle and rectal wall were unchanged by the procedure, and a 2°C rise was noted at a distance of 6 to 7 mm from the fossa cavity. The prostate capsule measurements were 5 mm from the edge of the vaporization margin, and a 4.3°C increase was noted there. Wattage was noted to increase both coagulation depth and width when applied to the canine liver during the same study. In general, coagulated tissue was not seen deeper than 2 to 3 mm from the prostatic fossa cavity. The largest change in temperature was noted in the irrigating fluid, which the authors concluded acted as a heat sink during the procedure.

Benjamin et al. (1997) defined chronic histopathologic changes in the prostate after vaporization. Throughout the healing process, no extension of the initial 2-mm necrotic area occurred. Re-epithelialization of the fossa was ongoing by week 3, with epithelial stratification at 5 weeks postoperatively.

Single-Cohort Studies.

Kaplan and Te (1995)reported on their first 25 patients treated with VaporTrode. Initial results were encouraging, with significant changes in

AUA-SS (17.8 to 4.2) and Qmax (7.4 to 17.3 mL/sec) at 3 months. Improvements in these values were seen at 1 week, and the catheter was removed at a mean of 14.6 hours from the end of surgery. Although all 14 patients who had erections preoperatively had retrograde ejaculation after the procedure, the lower cost associated with a shortened hospital stay encouraged more study. Te and Kaplan (1998) reported on their first 114 patients in 1998 and now had data out to 18 months in some patients. AUA-SS and Qmax changes were durable to at least 12 months. No patients required transfusion, and a mean hemoglobin decrease of 1.7 g/dL was reported. A high percentage of patients (89%) had their catheter removed within 24 hours, and although there was no increase in ED incidence, 84% of patients reported retrograde ejaculation. Other early adapters reported similar results (Narayan et al., 1996).

Studies naturally evolved into RCTs comparing TUVP to TURP, until Botto et al. (2001) reported on the use of bipolar vaporization. A Gyrus system (now part of Olympus) was the first to utilize bipolar vaporization, and the electrode had a riverboat wheel–type configuration. At 3 months, 42 patients reported a decrease in mean AUA-SS from 19 to 9 and an increase in mean maximum flow from 7.9 to 19.7 mL/sec. Urethral stricture occurred in two patients, and four patients reported dysuria. Bladder irrigation was required in one patient for up to 3 days, but no transfusions and an overall low risk for bleeding were reported.

Dincel et al. (2004) reported on 20 patients who had a vaporization using the PlasmaKinetic Tissue Management System (Olympus, Tokyo, Japan) using an older electrode. Improvements in AUA-SS (72%), QoL score (61%), and Qmax (111%) were noted. Prostate volume and PSA both decreased by a little over 50%, confirming significant tissue removal with the procedure. By measuring size and operating room time, they were able to calculate an average of 2.8 minutes for each gram of prostate vaporized.

Reich et al. (2010) reported on the contemporary mushroom-shaped PlasmaButton electrode (Olympus). No major intraoperative or postoperative complications were noted in this initial report. No clinical signs of fluid absorption were noted, and in the 12 patients for whom breath ethanol technique (Cummings et al., 1995) was used, no patient demonstrated an increase in ethanol concentration, implying minimal fluid absorption. Thirteen percent of patients continued platelet inhibitors throughout the procedure. Decrease in hemoglobin was minimal (1.1 g/dL), and no transfusions were needed, although 53% of patients needed postoperative irrigation, and one patient continued on the catheter for 8 days because of hemorrhage. Improvements in AUA-SS (61%), Qmax (174%), and PVR (77%) were all significant. One patient needed to be converted to TURP because of bleeding. This patient had a large gland (>100 g) and was in the first 5 patients treated in the study.

The single-center “Zurich Experience” described the results of this technology on 83 consecutive patients (Kranzbuhler et al., 2013). Each patient had a preoperative mean Qmax of over 10 mL/sec, which is atypical for LUTS/BPH treatment studies. This increased nonsignificantly to 14 mL/sec directly after catheter removal. After 6 weeks, all functional outcomes (AUA-SS, QoL, PVR) improved significantly when compared with baseline values, with further improvements compared with the 6-week values at 6 months for AUA-SS and QoL. The PSA reduced by an average of 60% at 12 months. In one patient with a large prostate (110 mL) a conversion to bipolar TURP was necessary because of obscured visualization by bleeding. Many patients (31%) were on antiplatelet medications during the treatment.

Comparative Studies

Monopolar Studies.

Hammadeh and Philp (2003) analyzed six early RCTs of monopolar vaporization and resection with 1 year of follow-up. **They were able to analyze over 200 patients in each group and found essentially identical changes in AUA-SS (–73% in both groups) and Qmax (216% in TUVP, 191% in TURP) between the different techniques.** Complication profiles were similar, although this was better studied by Poulakis et al. (2004). This study included patients anywhere within the first year of follow-up and compared occurrence of complication rates. **The authors found that TUVP had an improved profile compared with TURP with respect to operative duration, catheterization time, hospital stay, blood transfusion, and clot retention. Reintervention for LUTS/BPH and postoperative urinary retention was less likely to occur in the TURP group.**

Of these six early trials with 1-year follow-up, the study by Gallucci et al. (1998) included only patients who were obstructed on preoperative UDS. **At 3 months postprocedure, 92.5% of the TURP group was unobstructed by UDS standards, with 88.6% of the TUVP group unobstructed.** A small percentage of the TUVP group (1.4%) was still obstructed on UDS and underwent TURP, and no patient in the TURP cohort obstructed on follow-up UDS. Similar changes were noted in AUA-SS, Qmax, PdetQmax, and PVR between groups. However, a surprising 18.6% of the TUVP group had transient SUI, with 5.7%

of the total cohort having true SUI at 12 months after surgery. This surprising presence of incontinence was attributed to a possible unseen depth of coagulation near the apex that was unanticipated by the surgeon.

Although TUR syndrome was still a possibility because of the use of hypo-osmolar fluid, a study using ethanol-labeled glycine as the irrigant showed that vaporization led to less (672 mL) fluid absorption than resection (1347 mL, $P < .005$). This was thought to be caused by the sealing effect of vaporization techniques on the prostate sinuses and vessels.

Another of these six early trials followed patients to a total of 5 years after randomization to M-TURP or TUVP (Hammadeh et al., 2003). A total of 53 of the original 104 patients were analyzed. Both groups had statistically improved AUA-SS, QoL, PVR, and Qmax compared with their respective preoperative values. Although there was no statistical difference between groups at 5 years, trends toward an advantage with TUVP could be seen.

An RCT with 10-year results of patients undergoing TURP, contact LASER, and electrovaporization was published in 2010 (Hoekstra et al., 2010). Although 91% of patients could be accounted for, only 44% of the original 150 patients were available for analysis. Only TURP had a statistically significant improvement still at 10 years with regard to maximum flow rate and PSA. Although the TURP and contact LASER groups had prostate volumes roughly equal to the prostate volume at study start, the vaporization group was noted to have an increase at the 10-year mark compared with the baseline value (43 g from 28 g, $P < .05$). Although failure rates were not statistically different, TURP had a failure rate roughly one-half that of vaporization and contact LASER.

Bipolar Studies.

Multiple studies compared the newly utilized bipolar vaporization technology to M-TURP in RCTs. Reports on the PlasmaKinetic technology at 12 months (Karaman et al., 2005) and then at 36 months (Kaya et al., 2007) found a decrease in operating room and catheterization time, and although no patients in the bipolar group required transfusion, two TURP patients did. **AUA-SS improvement was statistically better in the vaporization group, although the TURP group had an uncharacteristically modest change in AUA-SS (only 45% reduction).** Although the early results seemed to favor bipolar vaporization, the 36-month results were less complementary. Although a bias related to follow-up could certainly be a factor in this change with only 40.5% of TURP patients and 65.8% of TUVP patients analyzed, results were heavily in favor of TURP. **At 3 years, TURP had improved AUA-SS (–74%) and Qmax (263%) compared with TUVP (–64% and 140%, respectively).** Three patients in the vaporization group required retreatment for BPH (one in the TURP group) and were overall less satisfied with treatment (48% vs. 60%). Differences in ED and retrograde ejaculation rates were not significant.

The higher rate of complications with more clinical efficacy was also noted by the higher recatheterization rate in the bipolar group (30% vs. 5%), with clot evacuation (19% vs. 0%) more often needed in the TURP group (Dunsmuir et al., 2003). Change in hematocrit was greater, and more irrigation was required in the M-TURP group in the results of Hon et al. (2006). Although no difference in systemically absorbed fluid was noted, four M-TURP patients required transfusion compared with no-vaporization patients.

Use of the TURis vaporization system seemed to further improve the results when compared with M-TURP. The single-center report from Geavlete et al. (2010) found that the PlasmaButton system led to better improvement in AUA-SS, QoL, and Qmax, with less significant hematuria, transfusion, and clot retention compared with M-TURP at 6 months. In their report at 18 months, they also included a B-TURP group (Geavlete et al., 2011). The bipolar vaporization group fared better than either TURP group with regard to capsular perforation, operating room time, and catheterization time. Outcomes such as postoperative AUA-SS, QoL, and Qmax were equivalent among all groups at the 18-month point, with all groups improved compared with baseline.

In a study of 55 Canadian patients randomized to either Olympus Plasma Button or Biolitec EVOLVE Diode laser vaporization (Biolitec Company, Jena, Germany), there were **similarities in safety and efficacy** (Skinner et al., 2017). However, costs were noted to be lower in the bipolar vaporization group along with shorter vaporization times.

Complications

Intraoperative and Perioperative.

It appears that the simultaneous vaporizing and coagulating properties of these vaporization technologies decrease the risk for intraoperative bleeding. Although there is **less blood loss** (Küpeli et al., 2001), the overall low risk for **transfusion** in most RCTs makes a statistical difference difficult to achieve, although a range of 0% to 2% was seen in a systematic analysis of RCTs (Ahyai et al., 2010). Other intraoperative complications like **capsular perforation** or **conversion to**

TURP are also rare, with conversions to TURP for bleeding seeming to occur more frequently in larger glands (Kranzbuhler et al., 2013).

Postoperative.

The largest postoperative risk associated with TUVP is the **need for retreatment** for LUTS and risk for unplanned **postoperative recatheterization.** The meta-analysis by Ahyai et al. found that 8.2% of patients required recatheterization after TUVP, which was among the highest rates of the analyzed techniques (Ahyai et al., 2010). The increased hemostasis achieved intraoperatively appears to lead to a decreased postoperative risk for **clot retention** (Geavlete et al., 2010), although 13% of TUVP patients in the series from Skinner et al. (2017) had clot retention, with 10% of the cohort requiring hospital readmission.

The inability to accurately judge the depth of energy dispersion led many early adapters to be concerned about inadvertent coagulation, particularly around the apex. Although not statistically significant, the slight increase in **incontinence** compared with TURP seen in the review by Hammadeh and Philp (2003) may be a product of the energy dispersion. Although still not rigorously studied, the increased risk for new **ED** (12% vs 5%) when compared with TURP also increased the concern of unwanted depth of coagulation. The risk for postoperative dysuria also appears to be more common in TUVP (Ahyai et al., 2010).

As described in the B-TURP section, the TURis/TUVis system uses the outer resectoscope sheath as the return electrode. In a study looking at the use of this system, a small series of calamitous complications were noted. In three consecutive patients, a patient had **bladder necrosis** leading to severe storage symptoms, and two patients had complete **urethral necrosis** with resulting urethrocutaneous fistula (Robert et al., 2012). We would recommend our preference for use of the PK system as opposed to the TURis/TUVis system.

Conclusion.

Prostate electrovaporization continues to be a viable option for treatment of LUTS/BPH. Although initially a very popular option for treatment of LUTS/BPH, widespread acceptance was likely tempered by questions about durability with a concern about dysuria and retreatment rates when used by itself. The excellent hemostasis of the procedure leads to excellent intraoperative visualization and is currently most commonly used as an adjunct to TURP for improved hemostasis after resection is complete. Although a significant innovation in its time, it appears that LASER vaporization is likely to supplant this as the preferred form of prostate vaporization for most providers.

Transurethral Microwave Therapy

Introduction and Concept.

The objective of TUMT is to locally thermoablate prostate tissue while maintaining normal temperatures in the surrounding, nontargeted tissue. This concept uses a specialized urethral catheter with an antenna that generates radially emitted electromagnetic (EM) waves. These EM waves are in the frequency of 915 to 1296 MHz and penetrate tissue to induce changes that produce localized heat. Treatments that achieve a temperature less than 44°C are designated *hyperthermia,* those that achieve a temperature greater than 44.5°C are designated as *thermotherapy,* and those that achieve a temperature greater than 65°C are designated as *themoablative* (Perlmutter et al., 1993).

Prostate parenchyma destruction occurs once a crucial "**thermal dose**" has been reached. This occurs as part of the multiplicative product of the temperature and exposure duration. Therefore, the critical values are the temperature achieved in the gland (not necessarily the same as the temperature generated by the machine) and the period over which that temperature is able to be maintained.

Optimally, the thermal dose should be confined to the prostate gland with minimal to no heating of the nontargeted, surrounding tissues such as the external urethral sphincter, bladder neck, and rectum. Collateral damage to these tissues will induce complications and may limit the treatment effect by inducing automatic shutdowns in the machine. Additionally, this misplaced heat may cause significant patient discomfort and inability to tolerate the procedure in the office setting.

The potential advantages of microwave technology include the convenience of an in-office procedure with rapid patient convalescence and minimal anesthesia requirements. It is likely the least operator dependent of the treatments for BPH with an easy learning curve.

Although patient selection is crucial to achieving results, there are particular factors that need to be examined when considering TUMT. Patient factors such as prostate volume, gland configuration, and the patient's ability to undergo a transurethral treatment under local anesthesia must all be carefully considered.

Prostates with marked middle lobe configurations may distort catheter positioning as the middle lobe will go largely untreated and project the microwave in unintended and unsafe locations. Prostate volumes at the extremes (<25 or >80 g) may impede uniform heating and lead to suboptimal results. Those smaller prostates may lead to unsafe heating of extraprostatic locations inducing complications such as sphincter injury. Importantly, patients with pacemakers, defibrillators, and pelvic/penile prosthesis should be excluded from treatment as these devices may undergo significant electrical or mechanical damage from TUMT systems. Results in patients who have undergone previous invasive BPH treatments may have unexpected transmission of the microwaves with dire results.

Significant differences exist among microwave treatment system designs. These include differences affecting antenna design, the heating pattern generated, and the treatment protocol; these should be carefully considered when choosing microwave treatment for patients. TUMT was pioneered using the Prostatron microwave system (Technomed International, France), and this design has been considerably investigated. The original design was later advanced to a "high-energy" (HE-TUMT) platform that inventors hoped would enhance the treatment effect. It appears that the antenna design dictates the heating pattern more than the frequency of wave energy used (Bolmsjö et al., 1996). Currently, the primarily utilized systems available are the CoreTherm (Prostalund, Lund, Sweden), Prolieve (Boston Scientific, Boston, MA), Prostatron (Urologix, Minneapolis, MN), TherMatrix (American Medical Systems, Minnetonka, MN), and Cooled ThermoTherapy (Urologix, Minneapolis, MN) (Fig. 146.13).

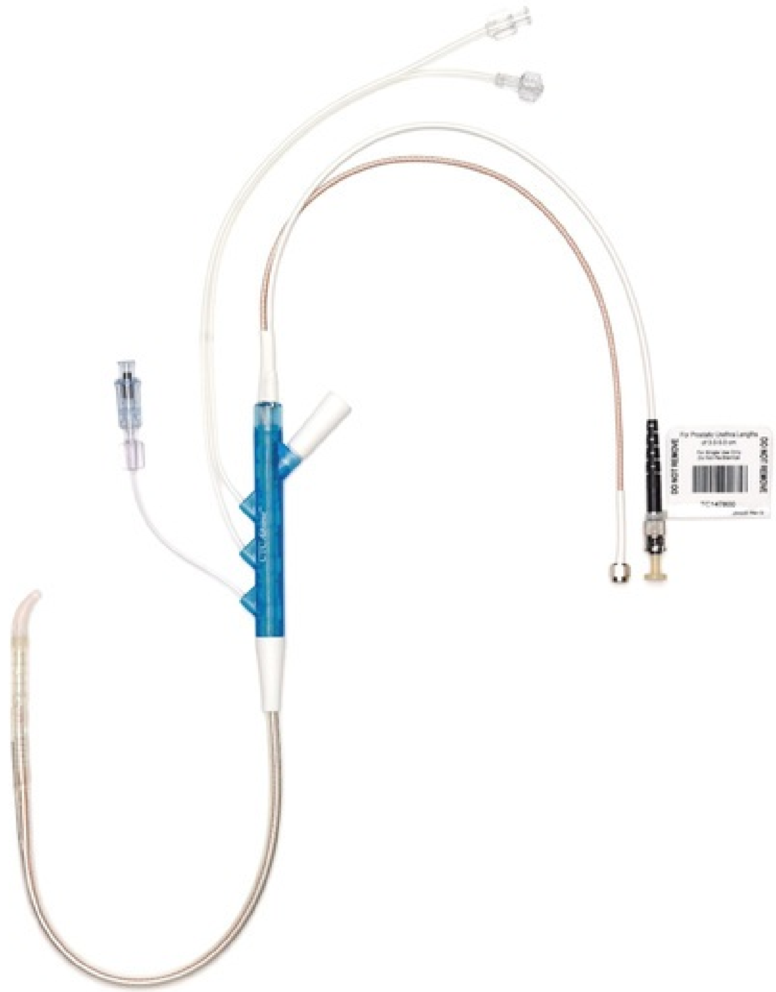

FIG. 146.13 Cooled ThermoTherapy transurethral microwave therapy catheter. (Courtesy of Urologix, Inc.)

The various TUMT platforms generate intraprostatic temperatures of 45°C to 70°C. The early systems supplied heat ranges from 42°C to 44°C and had rather disappointing results. As devices became more advanced, the intraprostatic treatment temperatures increased. The HE-TUMT nomenclature is applied to the more advanced devices at the higher end of this thermal range. Much of the advancement to using higher temperatures was precipitated by the ability of catheter cooling that would reduce urethral temperatures during use and reduce intraprocedural patient discomfort.

In these protocols, the energy was slowly increased to allow the patient to gradually adjust to the rising temperature. **When heat is applied to the prostatic parenchyma, there is a natural response with vasodilation of local vessels to physiologically dissipate the heat. Although it makes the procedure more tolerable, this slow increase of energy increased procedure**

times and decreased efficacy. The use of “heat shock” or high-intensity TUMT has been utilized to decrease this compensatory vasodilation. In this variation, the heat is delivered quickly so that the prostate vessels undergo thrombosis with improved heat entrapment in the prostate and decreased procedure times. This process is supported by the fact that prostates with a more significant vessel density are less likely to respond well to treatment in general (d'Ancona et al., 1999a).

Mechanism of Action.

The mechanism by which TUMT causes the reduction in LUTS/BPH is **not completely understood**. Multiple theories exist and are not mutually exclusive. These theories focus on altering prostate innervation or morphologic tissue changes in the prostate.

Nerve Degeneration/Sensory Changes.

The first of these theories appears to rest on the **dynamic concept of prostatic obstruction** wherein the tone of the smooth muscle of the prostate causes obstruction. This has been studied by investigators by examining tissue after TUMT wherein a biopsy was obtained. Ten patients underwent OP after TUMT with specimens evaluated using histologic immunohistochemical stains. The urethra was well preserved, and compared with controls, the specimens were found to have “disrupted” nerve fibers with axons rarely being found. The authors suggested that thermal damage to the adrenergic fibers essentially induced a “long-term α-blockade” (Perachino et al., 1993). This theory has few adherents.

The denervation may also be specifically targeted to the smooth muscle fibers of the prostate. A carefully controlled study using a prostate chip taken at the beginning of the case was stained using a nonspecific neuromarker protein gene product in both a control group of 10 patients and 10 patients who underwent TUMT 1 week before. Stained fibers were seen in all layers of the control biopsies. Almost all of the study group biopsies had nerve fibers in the lamina propria and epithelial layer. However, all but one study group specimen showed an almost complete absence of nerve fibers in the smooth muscle layer. The TUMT-treated patient without the smooth muscle nerve fiber changes had a small prostate (20 g). The findings of a preferential smooth muscle destruction of muscle fibers were noted even without a large degree of necrosis in the specimen (Brehmer et al., 2000).

Although this study noted changes in only some nerve fibers, there is still the possibility of a later-onset denervation of the other fiber groups. Animal studies looking at heat treatment of dog sciatic nerves found almost no histologic changes immediately after a heat treatment similar in duration and temperature to TUMT. However, segmental demyelination and axon loss was noted 3 weeks later, with changes persisting out to 1 year (Vujaskovic et al., 1994).

A more specific look at the subgroup of nerve fiber destruction in TUMT was completed by a group binding assay specific for the α_1 receptor. Twenty-five patients were included. Ten of these patients received TUMT before the cold-bunch biopsy and then subsequent TURP. Five patients had TUMT then retropubic prostatectomy. The control group underwent TURP (*n* = 10). **A statistically significant difference in the mean α_1-adrenergic receptor density was found between the control group (96.4 fmol/mg) and the TUMT-treated group (71.3 fmol/mg).** The receptors in all groups continued to have a similar dissociation constant (ability to bind their ligand) (Bdesha et al., 1996).

In an interesting study using electrical stimulation to examine the prostatic urethra in 13 patients before and after TUMT, the large majority of patients had improvements in symptoms, with the most favorable effect noted in storage symptoms (nocturia primarily). The decrease in urinary urge effectively was parallel to the increase in sensory threshold. The authors have postulated that the decreasing prostatic urethral sensation may lead to decreased input in the urethra-detrusor excitatory reflexes with an overall improvement in perception of voiding symptoms (Brehmer and Nilsson, 2000).

Morphology Changes.

When heat is applied to a specific portion of the prostate to a sufficient temperature and duration, an **area of necrosis is created**. This area of necrosis eventually contracts to form a scar and reduces overall prostate volume.

In a study looking at heat gradients in the prostate and histologic effects, patients underwent TUMT, followed by surgical tissue retrieval at varying later times. During the microwave procedure, temperature mapping was performed at multiple prostatic sites using fiberoptic thermosensors. Microwave treatments resulted in peak prostate temperature of 80°C with penetration of heat deep into the prostate parenchyma. Histologic changes were related to temperatures in the prostate. Mean temperatures increased rapidly with radial distance from the urethra to a maximum of 54°C at a distance of 0.5 cm from the urethra. As temperature increased beyond this distance from the urethra, temperature decreased exponentially but remained above 45°C at a distance of 1.6 cm radially. Pathologic findings were similar in all specimens with sharply circumscribed intraprostatic hemorrhagic necrosis at sites where 60 minutes of a minimum of 45°C was elicited by treatment. The borders of the areas of necrosis and the viable tissue were sharply demarcated. The mean range of this border was 0.5 to 2.5 cm from the urethra with a mean distance of 1.6 cm. They also noted, but poorly explained, an area of devitalized but noninflammatory tissue between the necrotic and normal areas (Larson et al., 1996).

A similar study explained this area between necrotic and normal tissue. Patients exposed to TUMT had an area of necrosis in a discrete area 20 to 25 mm from the urethra in the prostatic tissue. Within the area surrounding the necrosis, widespread apoptosis was noted (Brehmer, 1997). The root cause of the apoptosis could not be elicited in this study, but other work has shown that cell death results from apoptosis then necrosis based on an increasing heat load applied to the tissue (Harmon et al., 1990). Cultured prostatic stromal cells exposed to moderate hyperthermia of only 47°C for 1 hour confirmed the possibility of heat-induced apoptosis as 76% of cells were apoptotic. Cells also did undergo necrosis (14% of the sample), which further solidifies that there is a “thermal load” at which cells preferentially die of necrosis or apoptosis (Brehmer and Svensson, 2000).

The reduction in prostate volume appears to be related to the energy platform used as the LE protocol decreased by only 14%, and HE protocols decreased by 25% (Devonec et al., 1993).

Technique

Preoperative.

The benefit of a MIST selection is the ability to **perform the procedure in the office generally under just local anesthesia.** As always, the patient's ability to tolerate the procedure should be considered. Overnight admission is not needed, and patients are generally sent home directly after recovering from the procedure.

Cystoscopy is required before TUMT as the **presence of a median lobe is an exclusion criterion.** The median lobe would not be treated during the procedure, and its presence may also direct the catheter away from the midline altering the treatment. The prostatic length must be measured during the cystoscopy. A prostatic length of less than 25 mm is not suggestive of an enlarged prostate and will make the procedure technically challenging and perhaps unsafe. Prostate size should be between 30 and 100 g for TUMT.

Contraindications to the procedure include implanted pacemakers, defibrillators, inflatable penile prostheses, artificial urinary sphincters, and metal implants in the pelvis (e.g., a total hip replacement). Patients with urethral strictures should also be excluded from treatment as the catheter may be difficult to both place and verify correct position. Patients with a previous invasive BPH treatment should also be excluded as this is an untested group, and there may be unexpected projection of microwaves into aberrant locations. Comorbid conditions like peripheral arterial disease with claudication, prostate cancer, bladder cancer, and underlying neurologic disorders should also lead the patient and surgeon to choose a different treatment method.

Intraoperative and Perioperative.

The specialized catheter is inserted per urethra and advanced into position. The anterior wall of the rectum is monitored by the placed rectal thermometer probe. The preset program can then be started with an automated program running for the duration of the procedure and monitoring urethral and rectal temperatures. The balloon of the catheter remains in the bladder keeping the catheter in place while the EM waves are emitted into the transition zone of the prostate (Fig. 146.14).

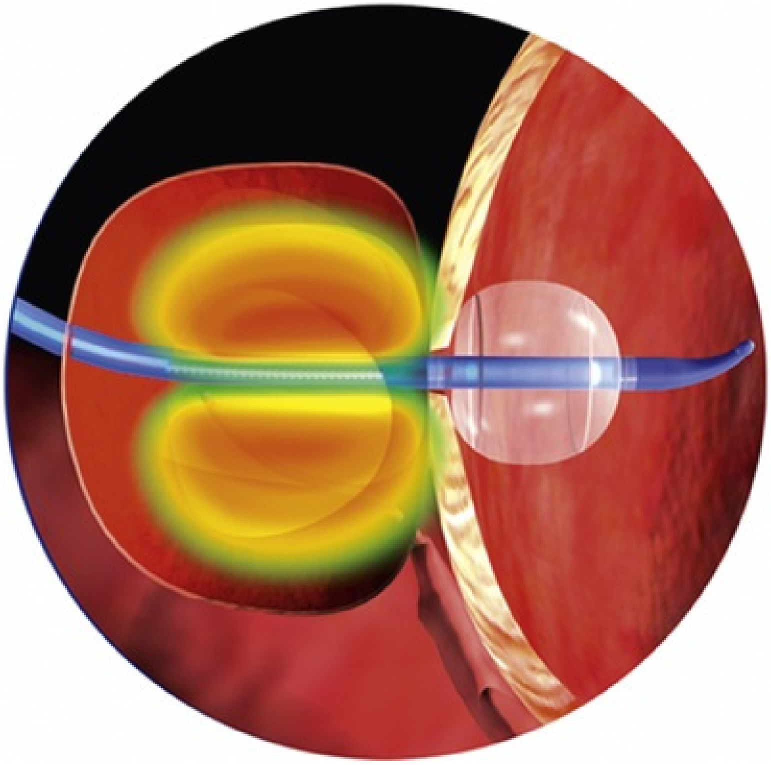

FIG. 146.14 Transurethral microwave therapy catheter treating the transition zone of the prostate. (Courtesy of Kevin T. McVary.)

One role that the surgeon plays in this procedure is to provide occasional "vocal" anesthesia to the patient in the form of calming the patient and providing reassurance to an awake patient. Continuous monitoring of patient comfort is critical. Unexpected discomfort may imply misplacement of the catheter. Significant injuries have occurred when such advice is not heeded.

Postoperative.

A benefit of TUMT is the benign postoperative course. **Perioperative complications are unlikely,** and patients do not require hospital admission. Patients may return home directly from the procedure, and convalescence is rapid.

Postoperative catheterization for a period of days is almost certain with previous generations of TUMT but is becoming less common. Higher-energy platforms have led to an overall lower rate of the standard transient postoperative urinary retention, but patients should be carefully counseled about this risk.

Outcomes.

Thermal or microwave therapy continues to be a treatment for BPH because of its relative ease of use and ability to be done as an office-based procedure. Because of the many different technology platforms, trials are difficult to group into larger analyses. **In general, the studies available are very heterogeneous and are frequently single-cohort and noncomparative trials having short-term follow-up, which should be judged carefully and individually**. An obvious lesson learned from these trials is that higher-power systems have superior results compared with their lower-powered predecessors.

Predicting Outcomes.

Initial work published on predicting outcomes of TUMT focused on the Prostatron 2.5 platform. This work defined early cutoff points to help guide the urologist in the care of patients after TUMT (d'Ancona et al., 1999a). **Outcomes were evaluated at 6 months, limiting the long-term scope of the study, but good response was independently predicted by preprocedural variables like younger age at treatment, larger prostate volume, and higher grade of BOO.** The energy used on the prostate during the procedure was also predictive of response but has less utility as it is post priori. Because PSA is a surrogate for prostate volume, pretreatment PSA was also found to be helpful in predicting outcomes in some studies (Djavan et al., 2000) but not in others (Laguna et al., 2002).

The ability to predict outcomes based on initial AUA-SS has been more difficult, and in one controlled study the proportion of patients achieving an AUA-SS of less than 9 (mild symptoms) was similar among patients in both the moderate and severe symptoms groups. Of the patients in the moderate symptoms group, 50% migrated to the mild group with many patients staying in the moderate group (38%) and some worsening to the severe group (12%). Of those already in the severe group by pretreatment AUA-SS, 14% continued to have severe symptoms, and many patients improved to the moderate (36%) and mild (49%) groups (Larson et al., 1998).

As many urologists may prefer this treatment in patients at higher risk for surgery, the utility in higher-risk patients has also been studied. In a study of a HE-TUMT device, the treatment was equally efficacious in high (3 to 4) or low (1 to 2) ASA scores (d'Ancona et al., 1999b), with no differences in post-treatment catheterization or ability to tolerate the procedure.

Single-Cohort Studies.

Despite the ease of use and relatively low complication rates, the major concern with TUMT is reduced overall LUTS improvement compared with other treatment options and the lack of durability. One vexing study using an older, low-energy (LE) machine (Prostatron 2.0) demonstrated initial significant improvement in patient level of satisfaction with treatment (Hallin and Berlin, 1998). **However, over the 4-year period there was a progressive, marked decrease in the number of satisfied patients from 62% at 1 year to only 23% at 4 years.** The initial improvements in symptoms and increase in flow rates were followed by reversal of these findings at 4-year follow-up. Additionally, **two-thirds of the patients in the study received additional BPH treatment within the 4 years they were followed.** These concerns were further justified when studies showed a cumulative risk for subsequent TURP retreatment of 40.5% at 5-year follow-up and a percent cumulative risk for any retreatment (including α-blockers) of 57% (Keijzers et al., 1998). Another LE-TUMT protocol confirmed high retreatment rates, with 35% of patients requiring additional treatment within 3 years (Daehlin and Frugard, 1999).

Studies of early, LE systems looking at changes in both subjective and objective measures of improvement have found varying results. **Almost all of the LE studies showed an improvement in subjective symptom scores but often without changes in objective measurements like maximum flow, residual urine, or UDS features like peak detrusor pressures.** With the upgrade to HE devices, changes in objective metrics became more common. Although more energy is used, the HE protocols are still well tolerated under local anesthesia (Eliasson and Wagrell, 2000). When heat shock protocols are used, the shorter duration of treatment also leads to an increased initial pain score but a similar post-treatment pain score (Francisca et al., 2000).

Using an HE-TUMT device (Targis), a group of investigators demonstrated significant improvement in AUA-SS, QoL score, Qmax, and PVR that was durable at 24 months (Thalmann et al., 1999). UDS was routinely performed in patients, and improvements in mean detrusor opening pressure and detrusor pressure at maximum flow were also significantly improved 6 months after treatment. A cavity in the prostatic fossa (similar to those seen in patients after TURP) was noted in 77% of patients, and TRUS demonstrated a decrease in prostate volume from 57.6 g to 42.4 g. Despite these positive results, 13% of patients required retreatment.

In one of the most recent TUMT studies, the findings of many previous studies were reiterated (Mynderse et al., 2011). The Cooled ThermoCath catheter with a Targis system was used under a 30-minute heat shock protocol. The percentage of patients requiring any sort of postoperative catheterization (50%) was less than previous TUMT studies, and only 3% of patients required catheterization for more than 7 days. **At the final follow-up at 5 years post-treatment, a 43% improvement in AUA-SS and 39% increase in Qmax was noted. Unfortunately, 29% of patients required additional BPH related treatment with 9% of the overall cohort requiring surgical treatment.**

When summarizing symptomatic improvement with HE-TUMT, **patients will have a 60% reduction in symptom scores noted at 3-month follow-up**. This tends to become slightly better at the 6- and 12-month points. There is no significant difference between HE-TUMT devices in reduction of symptoms. **At 3 years, symptom improvements worsen to only 45% improvement, but retreatment is seen in close to 20% of patients** (Floratos et al., 2001)**. The aggregated changes in Qmax represent a 50% improvement seen at 3 months and stable at 12 months** (Gravas et al., 2003) **with studies rarely reporting a post-treatment Qmax greater than 15 cm/sec.**

Patients who had urinary retention represent a more challenging BPH group to treat. In one of the first HE-TUMT studies on men with AUR, 94% of men were able to spontaneously void at 4 weeks after treatment (Djavan et al., 1999a). Although no pressure-flow studies were obtained, this group likely represents a cohort with functional detrusor muscle. Contrary to this, a study that included chronic urinary retention patients, the 1-year failure rate was 25%, and mean catheterization time was 38 days (Floratos et al., 2000). In a study of surgically high-risk patients in acute urinary retention, 87% were able to void spontaneously (3 months postprocedure), with 7.3% experiencing repeat urinary retention within 2 years (Berger et al., 2003).

Comparative Studies

TUMT vs Sham.

Many sham-controlled studies have been performed involving TUMT. This is likely caused by the low morbidity of producing a sham equivalent arm as minimal anesthesia is required. These sham studies are interesting as they highlight the placebo effect present in BPH treatment.

The placebo effect of a sham study is most notably highlighted in Nawrocki et al. (1997). In this study, patients were randomized to one of three groups—TUMT, simulated TUMT, and observation—with 6-month follow-up. The simulated TUMT group underwent a process identical to TUMT, except the generator ran a simulated program that included machine noise, screen readouts, and heat emission by a pad placed under a blanket. No statistical changes were noted in objective measures like pressure-flow outcomes or urodynamic variables. **Surprisingly, there was a statistically significant decrease in AUA-SS for both the TUMT group (19 to 9.5) and the simulated TUMT group (17.5 to 9.5). The untreated group did not note this change (AUA-SS changed from 18 to 17).** These results are interesting in that they highlight the perceived benefits of TUMT (in terms of reported AUA-SS changes seen in both the TUMT and simulated TUMT group) but showed no objective changes in any of the groups. Interestingly, just performing a sham treatment reduced AUA-SS in a significant fashion.

Other prospective sham studies (without untreated groups) did show improvements in peak flow to complement the decrease in AUA-SS. Studies of the Targis thermoablation system (Larson et al., 1998) and Dornier Urowave system (Roehrborn et al., 1998a) both exhibited this response with overall similar findings. The Dornier Urowave system provided decreases in the AUA-SS for both the treatment and sham groups. The treatment group AUA-SS decreased from 23.6 to 12.7 at 6 months, with a decrease of 23.8 to 18.0 in the sham group. Although both study groups had a significant decrease, the change in the treatment group was statistically superior. Peak flow improved in the treated group (7.7 to 10.7 mL/s) and untreated group (8.1 to 9.8 mL/s), with the treated group being statistically superior.

The study of the Targis system had a similar pattern of findings. Both the treatment and sham groups had statistically significant improvements in AUA-SS from a mean of 20.8 to 10.5 in the treatment group with a lesser but still significant decrease in the sham group (21.3 to 14.3). Flow rates improved from 7.8 to 11.8 mL/sec in the treated group, with a less impressive increase in the sham group (7.8 to 9.8 mL/s) (Larson et al., 1998).

TUMT vs α-blocker.

Some authors have stated that TUMT should stand on the continuum of BPH treatment in between medical management and more aggressive treatments like TURP and OP (Djavan et al., 1998a)**. The underlying precept of this view is that the single, low-risk procedure could remove the hassle and cost of years of medical treatment.** Although patients undergoing TUMT do have a frequent need for additional BPH retreatment, the results are not far different from those failing medical management. In an investigation of retreatment in patients using α-blockers, results were assessed at 3 years with failure rates of 27% (tamsulosin), 37% (alfuzosin), and 49% (terazosin) noted (de la Rosette et al., 2002).

One RCT has compared TUMT with α-blocker (terazosin). Mean AUA-SS and Qmax were improved for both groups, with TUMT having a more pronounced effect at both 6 and 12 months. The TUMT had a 35% improvement in AUASS compared with α-blockers and a 22% improvement in Qmax. The terazosin group had a sevenfold higher actuarial treatment failure rate (Djavan et al., 2001). However, the definition of failure was qualitatively different between groups, and this should be interpreted cautiously.

TUMT vs TURP.

Concerns about the durability of TUMT are common despite the improvement seen in uncontrolled studies and sham comparisons; many studies had higher than acceptable retreatment rates, with patients often failing TUMT only months after surgery. As always, comparison to the “gold standard” treatment is necessary before any treatment is considered standard practice. Although changes in the energy delivered by the system improved many patient outcomes, comparison to TURP further highlighted the weaknesses of the TUMT intervention.

A randomized trial using the HE-TUMT Prostatron 2.5 system included 6 months of follow-up (Ahmed et al., 1997). The primary endpoints for the study included AUA-SS, maximum flow, residual urine, detrusor pressure at maximum flow, and prostate volume. All outcomes in the TURP group were improved. **The TURP group was improved in all outcomes, and in the TUMT cohort, only the AUASS was improved with multiple other factors worsening. Generally, the adverse events were higher with TURP, but the TUMT group had a prolonged postoperative retention.**

Contemporary studies of the same machine had very different results. At 1 year of follow-up, there was a decrease of 78% in the TURP in the Madsen-Iversen symptom index with a decrease in the TUMT group also noted (68%). Maximum flow rate improved by 100% (TURP) and 69% (TUMT), and both groups had relief of bladder outlet symptoms by urodynamic parameters. Although the effects in the TURP group were pronounced in all accounts, they were not statistically different from the TUMT group. Groups were equivalent on need for retreatment, but the TURP group needed more frequent returns to the operating room for coagulation (3 vs. 0 patients). The TUMT group had a longer duration of catheterization, with one patient requiring 35 days. Correspondingly, the TUMT group had an increased risk for postoperative UTI, with one patient requiring readmission to the hospital for infection. Additionally, postoperative irritative symptoms were more common in the TUMT group (29% vs. 14%) (d'Ancona et al., 1997).

A similar randomized study with longer follow-up (median 33 months) displayed improvements in the TUMT group with respect to urinary flow (improved 64%) and AUA-SS reduction (–60%), although these paled in comparison with those in the TURP group (+214% in Qmax and –85% in AUA-SS). With a longer follow-up, the retreatment rates in this study should be carefully examined. A retreatment of 19.8% in the TUMT group and 12.9% in the TURP group were not statistically different (*P* = .28), but the reasons for retreatment appeared to be caused by different etiologies. In the TUMT group, 10 of the 14 patients underwent additional BPH treatment (TURP, LASER prostatectomy, TUNA, α-blockers), whereas only 1 of the 8 patients in the TURP group required this type of retreatment (α-blockers). Although these did not have different statistical needs for additional treatment of any kind, it would appear that more patients in the TUMT group needed retreatment for residual BPH (Floratos et al., 2001).

More recently a multicenter, randomized trial released 5-year follow-up results to complement the previously released results at 1 and 3 years. At the initial 12-month follow-up, they concluded there was no statistical difference between treatments in Qmax, detrusor pressure, and prostate volume, but the change in each of these was more pronounced in the TURP patients. A longer postprocedural catheter time (14 days vs. 3 days) was seen in the TUMT group. **Adverse events were graded according to severity, with the TUMT group undergoing more mild-moderate events (often characterized as "expected") and the TURP group having more "serious" events (i.e., clot retention requiring readmission)** (Wagrell et al., 2002). The 5-year data (66% of the original patients available) showed that 16% of the TUMT group was considered a treatment failure, with only 6% of the TURP group being considered a failure of treatment (Mattiasson et al., 2007).

In studies using UDS to classify the obstruction, TURP proved superior. A comparison at 30 months of HE-TUMT to TURP found that one-third of the TUMT patients remained "obstructed" on UDS, and only 14% of the TURP group maintained this UDS classification of "obstructed" (d'Ancona et al., 1998).

A recent Cochrane review of TUMT analyzed the 6 trials comparing TUMT and TURP. **The pooled mean AUASS of TURP decreased by 77%, with a 65% reduction seen in TUMT. The pooled mean peak urinary flow increased by 119% with TURP and 77% with TUMT, with a weighted mean difference favoring TURP by 5.08 mL/sec** (Hoffman et al., 2012).

In a study comparing QoL outcomes between TURP and TUMT results, a 41-question assessment was completed before and after surgery. Metrics of overall well-being, urinary symptoms, sexual function, daily activities, social activities, and psychological well-being were assessed. Both treatment modalities had a significantly positive effect on aspects of life, with perception of activities of daily living along with perception of urinary difficulties improving. Although both treatments were efficacious in improving quality measures, TURP did have a greater impact than TUMT in the 147 patients examined (Francisca et al., 2000).

Complications

Intraoperative and Perioperative.

Much of the argument for the use of TUMT over TURP in the treatment of BPH is the **decreased complication rate, particularly in the perioperative period.** Higher rates of early retreatment for procedural complications are seen for TURP compared with TUMT. Unfortunately, most TUMT trials do not have a comprehensive review of adverse events. This leads to a potential bias as those reporting may have had lower than average complication rates.

In almost all cases, patients are **able to tolerate the procedure** in an office setting. Patients reporting a sensation of local, perineal warmth or an urge to urinate are common but do not limit the ability to complete treatment. Although some may advocate sedatives or analgesics for every patient, a randomized comparison proved that topical anesthesia alone was sufficient (Djavan et al., 1998b).

With careful monitoring and correct placement of the catheter and rectal temperature probe, **injury to surrounding structures** should not occur. Errant reports of severe complications like penile necrosis and urethral fistulae have been seen in the FDA registry but are likely caused by improper catheter placement or poor monitoring of the patient during the procedure (Walmsley and Kaplan, 2004).

Postoperative.

Contrary to the perioperative profile described earlier, the long-term complication rates generally favor TURP. Retreatment rates for BPH are significantly higher for TUMT than for TURP. Retreatment rates have been discussed at length earlier and will not be further elaborated on here.

Complications like postprocedural **hematuria leading to transfusion** are rare after TUMT. **Urethral stricture** and **bladder neck stenosis** are occasional complications, with a cumulative risk of about 2% (Floratos et al., 2001). **Transient incontinence** is seen in about 2% of cases, with permanent incontinence being extremely rare.

Post-treatment convalesce is fairly rapid, with a mean recovery at home of 5 days and 55% of patients spending less than 3 days at home (Ramsey et al., 1997).

Prolonged catheterization times and **acute urinary retention** with the early generations of TUMT were the rule and not the exception. Almost all studies demonstrated an increased catheter duration compared with TURP, and catheterization durations of up to 1 to 2 weeks are not unusual (de la Rosette et al., 1997).

In an effort to reduce the catheterization times and postprocedural symptoms, attempts were made to use biodegradable urethral stents (Dahlstrand et al., 1997), temporary urethral stents (Djavan et al., 1999b), and periprocedural α-blockade (Djavan et al., 1999c). α-Blockade reduced postoperative retention from 12% in TUMT alone to 2% in TUMT with periprocedural α-blockade. In a prospective comparison of α-blockers and urethral stents, stents were more effective at 2 weeks, reduced symptom scores, and improved flow rates. No patient with a urethral stent was in retention 1 week after TUMT (compared with 11% of patients with TUMT alone), but 11% of patients with a urethral stent needed early removal because of clot formation or stent migration (Djavan et al., 1999d).

Coinciding with prolonged catheterization, **urinary tract infection** in the post-TUMT patient is a common finding. Reports of incidence are sporadic, but numbers as high as 13.5% (Dahlstrand et al., 1995) have been published, with most large studies reporting an incidence in the low- to mid- single-digit percentages.

With HE protocols, the **effects on sexual function** have been more pronounced. Although not rigorously studied with validated questionnaire data from preprocedural and postprocedural periods, few reports have high rates of sexual dysfunction. Most studies had no incidence of **ED,** although these data should not be frequently quoted. One report found only 5% of patients with new ED (Kirby et al., 1993), and 55% of patients still graded sex as "very satisfying" (Francisca et al., 1999). In the TURP cohort of this comparative study, only 21% of the TURP group gave the "very satisfying" answer.

Reports of **ejaculatory dysfunction** after TUMT follow a similar pattern but have also not been rigorously studied. Most have reported low event numbers, with many reporting no change at all. A fairly high (44%) incidence was reported in one study, which stands out against otherwise benign reports (de la Rosette et al., 1996). A study dedicated to sexual outcomes found that 74% of the patients had antegrade ejaculation after the procedure (Francisca et al., 1999).

In the Cochrane review of TUMT versus TURP, TUMT was associated with a decreased risk for retrograde ejaculation, stricture treatment, hematuria, blood transfusion, and TUR syndrome. TUMT did have an increased risk for dysuria, urinary retention, and BPH symptom retreatment (Hoffman et al., 2012).

Conclusion.

TUMT is a technology that is used to apply heat to the prostate, and its mechanism of action is still in debate decades later. Although a technically easier procedure than many of its counterparts, it carries a **potentially prohibitive need for retreatment** because of persistent LUTS/BPH. Although it does have a favorable overall complication profile compared with TURP, the risk for eventually requiring retreatment needs to be weighed carefully when considering TUMT for a patient. One should note that any long-term durability and measure of voiding symptoms after TUMT suffers from selection bias as it only includes patients who were responders and did not advance to other treatments.

Overall, the summation of the large volume of literature on TUMT does support the place of TUMT in the continuum of treatment for BPH although in a lower-efficacy/low-risk location. The patient generally will experience an improvement in symptoms that is not as pronounced for more invasive procedures with a low risk for adverse events. The use of this technology as a replacement for medical therapy is reasonable. How the influx of newer office-based MISTs changes the use of TUMT in the future is still yet to be seen.

Transurethral Needle Ablation of the Prostate

Introduction and Concept.

The TUNA system is composed of an RF generator, a disposable urethral endoscopic catheter that attaches to a reusable catheter handle, and an optics system. The treatment concept and design was originally FDA approved in 1996 and was significantly updated in 2003. The procedure was first performed in 1993 (Schulman et al., 1993).

The specialized urethral endoscopic catheter is used for this procedure and is attached to a reusable control handle. This rigid catheter is placed into the urethra and advanced into the prostate under direct vision as this device utilizes an embedded lens that is at either zero or 15 degrees based on surgeon preference. Once in position, needles are deployed from the end of the catheter into the prostatic parenchyma. The needles deploy at an acute angle to each other and at a right angle to the longitudinal axis of the catheter. The needles have a variable length that can be adjusted to different prostate widths and sizes. The urethra is protected from heat energy because of PTFE/nylon sheaths that extend to cover the proximal portions of the treatment needles. The urethra is untreated and not denuded, so the patient should theoretically have minimal local symptoms. The protective sheaths also have a thermocouple that monitors the temperature at the edge of the sheath. The needles and shield are adjusted by controls on the catheter handle (Figs. 146.15 and 146.16).

As with ultrasonography, the lower the frequency generated, the greater the depth of tissue penetration of the RF energy (or sound waves in the case of ultrasonography). **The LE monopolar RF has excellent tissue penetration. The RF flows into the prostate parenchyma and interacts with the water molecules in the cells. This interaction creates localized heat around the needles.** The heat energy has a fairly low dissipation into unwanted tissue as the temperature decreases when the distance from the needles increases (temperature decreases by a factor of 1/radius^4). **When an adequate amount of heat is applied to the tissue, a spheroidal area of coagulative necrosis is created, which later undergoes cavitation.** This cavitation should lead to an overall size decrease in the prostate, although there is some thought that the treatment area actually later becomes scar tissue and does not lead to a significant decrease in prostate size. Retrograde ejaculation should be minimized as the bladder neck is unaffected.

The original systems were reactive to change in tissue impedance, and the platform redesign called the Precision Plus (now marketed by Urologix, Minneapolis, MN) introduced a system in 2003 that **measures both temperature and impedance.** In the older, entirely impedance-based system, the generator delivers energy while the impedance of the tissue between the needles is monitored as if part of a completed circuit. The impedance increases as the tissue between the needles desiccates and is destroyed. Once the impedance reaches a certain level, the treatment in this area is complete as the tissue is desiccated and no longer able to conduct current. The level of output energy delivered was operator dependent, and the rate and amount of energy delivered were vital to creating a successful lesion. If too little energy was delivered, the lesion would be small and incomplete. If the energy was delivered too quickly, tissue would desiccate too rapidly with an inadequate total thermal load (a product of delivered energy and time), and the treatment would be less effective. The size of the created lesions is proportional to the area of tissue in contact with the needle and the quantity of energy delivered. In an MRI study looking at changes in prostate volume, the mean area of necrosis was 7.56 cc (constituting 11.28% of total prostate volume) (Huidobro et al., 2009).

The modern system is more straightforward. In this system, the needles have thermocouple electrodes at the tips that are able to monitor the temperature of the target tissue while the overall tissue impedance is also monitored. Currently the only device available in the United States is marketed by Urologix.

Technique

Preoperative.

TUNA is indicated in men with bothersome LUTS who are refractory to medications with prostate sizes up to 80 g. Sterile urine should be verified before the procedure. TUNA is not recommended in patients with metallic pelvic prostheses. Additionally, a defibrillator or a pacemaker may receive EM interference from the procedure, and they should be considered a contraindication.

A benefit of TUNA is that the procedure can be done under local anesthesia. This can be done safely in the office setting without postoperative admission, although a 23-hour admission is not uncommon after the procedure. The procedures should be done with a minimum of viscous urethral lidocaine, but oral or intravenous sedation may also be of benefit to the anxious patient. There is significant variation in the degree of anesthesia given by providers of this type of care (Bouza et al., 2006).

A **preprocedural TRUS** is performed to gauge the prostatic size, anatomy, and prostate width. Cystoscopy is also performed routinely to rule out any bladder pathology and verify the distance from the bladder neck to the verumontanum.

The **prostate length and width are of particular importance** as the length will determine the number of levels at which needle deployment will be required. Prostates of 3 cm or less are treated at two different zone levels. A length of 3 to 4 cm will require three levels of treatment, with prostates larger than 4 cm requiring four zones of treatment. The length into the prostate that the needles are deployed is based on the prostate width.

Intraoperative.

The patient is positioned in the dorsal lithotomy position on a table. A grounding pad is applied to the patient's back in the lumbar area or over the sacrum. The anesthesia of choice is then given. The viscous lidocaine is given per meatus with a penile clamp left in place to keep the lidocaine in the urethra for 10 minutes. If a periprostatic block is elected, then this is done similar to the block for a prostate biopsy.

The specialized cystoscope is placed per urethra under direct vision. The needles are deployed using controls at the catheter handle base and can be rotated 180 degrees to engage the prostate lobes based on these controls. The length of the Teflon shield on the needles should be adjusted so that the prostatic urothelium is spared from any treatment effects (usually 4 to 6 mm). The scope often needs to be pressed into the lobe for the needles to “grab” and keep the catheter from being pushed away from the lobe as the needles are advanced. Needles are deployed directly laterally into the lobes (at 8/10 o'clock position and 2/4 o'clock position).

Once deployed, the needles are placed through the urethral mucosa into the prostatic parenchyma. Once the ideal needle location is verified and the Teflon sheaths have been advanced to protect the urothelium, the generator is activated. Thermocouples monitor the urethral and needle-tip temperature. The energy is slowly increased until the tissue temperature is reached. The needle tips are employed to be more than 6 mm from the prostatic capsule to ensure no damage to structures outside the capsule. The needle tips are then heated to at least 100°C. It takes only 20 to 30 seconds to reach the treatment temperature, and once it has been achieved the area is treated for 2 to 3 minutes. The delivered energy is adjusted by the software to maintain the temperature.

The needles treat a discrete area around and between the tips creating an area of coagulative necrosis. To treat the entire gland, multiple planes in each gland must be treated. **The number of zones and planes required for treatment is dependent on prostate size and shape** (Fig. 146.17). Generally, the needles are first deployed in a plane 1 cm below the bladder neck into the parenchyma, with subsequent placements at 1-cm intervals in the prostate and the last placement 1 cm proximal to the verumontanum. The length that the needle is deployed into the prostate parenchyma is calculated by the software program based on the dimensions of the prostate including the width and other measurements from the preprocedural TRUS.

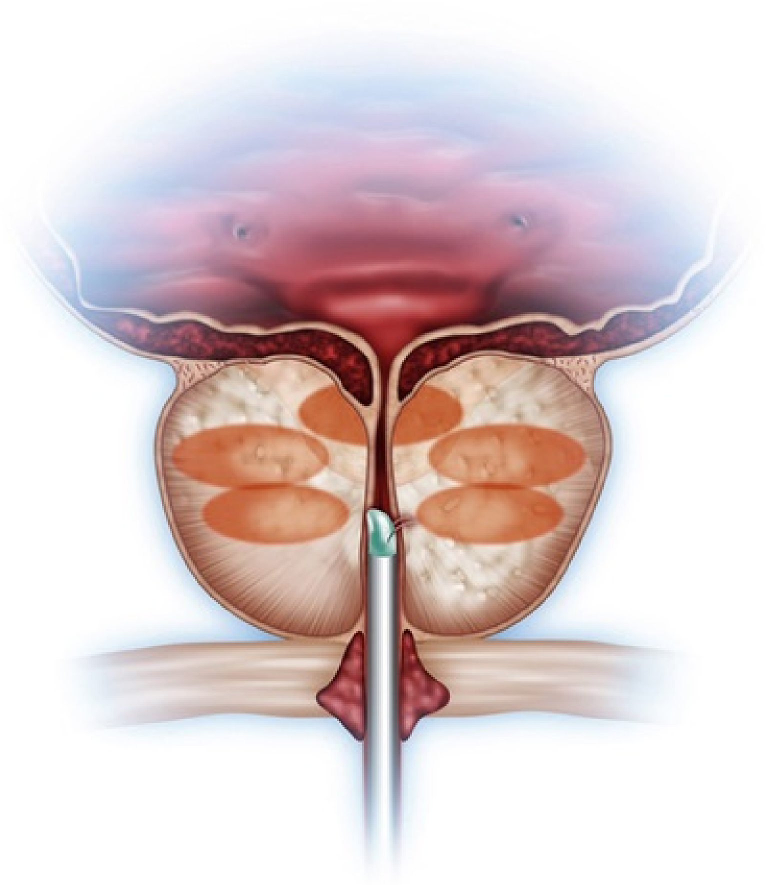

FIG. 146.17 The treated prostate in transurethral needle ablation. (Courtesy of Kevin T. McVary.)

During treatment, temperatures near the needle tips will rise to 115°C within 20 seconds of generator activation. Temperatures are then maintained at this level for 2 to 3 minutes. This temperature and duration should cause the desired local tissue necrosis. The tissue temperature should be monitored throughout the procedure along with the urethral temperature. **The machine is automatically**

equipped to shut down if the urethral temperature increases to a potentially harmful level. Treatment is complete once all of the predetermined areas of the prostate have been treated.

Postoperative.

Patients are able to return home after the procedure, and convalescence is rapid. A few days of irritative symptoms are normal and likely minimized because of the minimal effacement of the urethral mucosa. If a urinary catheter is placed, it is maintained between 1 and 3 days based on surgeon preference. Antibiotics can be used for up to 2 weeks, and NSAIDs are continued for 10 days. The empiric antibiotic treatment is to avoid bacterial proliferation forming an abscess in the cavitated necrosis of the post-TUNA prostate (Barmoshe et al., 2006). Most patients are able to return to work in 2 to 3 days.

Outcomes.

Although TUNA does show improvements in both subjective and objective measures of voiding, the results are less impressive than those found in TURP. **Studies utilizing UDS frequently show that patients do not migrate from an obstructed classification.** A prohibitive need for retreatment also attenuates enthusiasm. Comparisons to TURP are found in the literature, but no such comparisons of TUNA to medical treatment exist. Although it may have an overall lower rate of efficacy, the treatment is relatively safe with few if any major adverse events.

Single-Cohort Studies.

There is a consensus that TUNA treatment provides improvements in both subjective and objective measure of voiding at least in short-term studies. However, there are a **surprising lack of long-term data** published, with only a handful of reports on patients further than 2 years from procedure.

Rosario et al. (1997) completed a comprehensive study primarily utilizing an early generation of TUNA devices. A total of 71 patients who were all found to be obstructed on pressure-flow studies were enrolled. Patients completed a 5-day voiding diary before the procedure and before each visit. Analysis completed at 12 months found a variety of positive results. **Significant improvement was seen in multiple subjective outcomes including AUA-SS (21.9 to 10.6), QoL score (4.8 to 2.2), number of daytime voids (8.7 to 5.6), and number of nighttime voids (2.7 to 1.7).** At 1 year, 45 of the original 71 patients underwent repeat UDS. A statistical, but clinically questionable, decrease in PdetQmax was noted (97 to 82 cmH_2O). None of the patients were able to move into the "unobstructed" portion of the Abrams-Griffiths nomogram, and 78% remained "obstructed." No significant change in prostate volume or PSA was noted. Only 54% of patients were "completely satisfied" with the treatment. A total of 22 (30.1%) went on to additional treatment with TURP.

The study by Steele and Sleep (1997) reported a more impressive decrease at 2 years in PdetQmax (92.4 to 58.9 cmH_2O). Maximum flow increased from 6.6 to 11.2, and AUA-SS decreased from 22.4 to 9.5. A total of 6 patients from the initial 47 patients required TURP during the study period. They attempted to determine any preprocedural values that predicted failure but were unable to find any significant correlations.

In one of the larger noncomparative studies, Roehrborn et al. (1998b) studied 130 patients prospectively. Improvements were once again seen in AUA-SS (23.7 to 11.9) and Qmax (8.7 to 14.6 mL/s). **Surprisingly, 13.1% of patients reported an improvement in AUA-SS with either a decrease or no change in their peak urinary flow. Conversely, 4.8% of patients noted an increase in Qmax without an improvement in AUA-SS.** Treatment duration was quick (mean 37.4 minutes), and although no patient required general anesthesia to complete the procedure, 22% reported some degree of pain. Most patients (59.2%) were able to void after the procedure. Of those who required catheterization, the mean duration was 3.1 days, although one patient required a catheter for 35 days.

In one of the few studies with data beyond 2 years, Zlotta et al. (2003) enrolled 188 patients into a multicenter study. At 5 years postprocedure, 121 patients were still available for analysis, with another 10 patients reaching 4 years. **Significant improvements were seen in Qmax (40.7%), AUA-SS (–58.4%), QoL score (–55.1%), and PVR (–31.8%). Patients had a fairly large prostate at baseline with a mean size of 53.9 g, and, again, no appreciable change in volume was noted with the procedure.** Additionally, the PSA did not have any significant change with treatment. Of the 176 patients (2 deaths, 10 lost to follow-up) remaining at final analysis, 23.3% required some form of retreatment. Of the total cohort, 6.4% received additional medical treatment, 3.7% underwent a second TUNA, and 11.1% underwent unspecified surgery.

In studies looking at TUNA use in patients with AUR, results were surprisingly positive. A total of 20 patients were included, and inclusion criteria included good detrusor function on UDS. All patients had also failed a trial of void after their initial catheterization. Although all patients remained obstructed by the Schafer coefficient after the procedure, 17 of the 20 were able to spontaneously void. Five patients still progressed to receiving TURP for symptoms (Millard et al., 1996).

In their review, Bouza et al. (2006) analyzed the available data and found that **TUNA could reliably reduce symptom scores and QoL values by 50% to 60% compared with preprocedural values.** They concluded this improvement was maintained over time with a downward trend noted after 3 years. **In objective parameters, improvements were more modest but still statistically significant. A 30% to 35% improvement over baseline values was noted in objective measures like Qmax, with even poorer outcomes on measures obtained from UDS.** Of studies assessing patients with acute or chronic AUR, 70% of patients could spontaneously void within the first few weeks of the procedure.

Comparative Studies.

Very few studies comparing TUNA to other treatments exist, and of these comparative studies a minority have been done in a randomized fashion. Although most studies report the standard subjective and objective measure of voiding, complications are irregularly reported. Follow-up beyond 3 years is rare in any type of study, and conclusions on long-term durability of this procedure should be made with caution.

TUNA vs. other MISTs.

In a nonrandomized treatment protocol comparing patients selecting TUNA, TUMT, or high-intensity focused ultrasonography (HIFU) for treatment of BPH, discouraging results were found with regard to MIST treatments (Ohigashi et al., 2007). Although statistical decreases were seen in all three MIST treatments with regard to AUA-SS at 6 months after treatment, with HIFU (52%) performing better than TUNA (45%) or TUMT (38%), all three treatments no longer had statistically significant improvements at 24 months. Although a large number of patients were lost to follow-up, retreatment rates were surprisingly high, with 34% of TUMT, 36% of TUNA and 58% of HIFU patients requiring retreatment by 3 years. At 5 years, retreatment ranged from 54% to 68% for the groups. In an interesting analysis, they found that an initial Qmax of less than 10 mL/sec and an AUA-SS greater than 19 were risk factors for retreatment. This is suggestive that patients with more severe metrics of BOO may be better suited with a different form of treatment. Although data was only accumulated for 3 months post-treatment in this nonrandomized trial, Arai et al. (2000) found that patients undergoing TUNA were more likely to rate their satisfaction with the procedure higher than those having TUMT.

A few studies have compared TUNA to TUVP (Schatzl et al., 1997, 2000; Minardi et al., 2004). The analysis of these outcomes reports that TUVP has a higher risk for adverse events with more significant improvements in subjective and objective voiding outcomes (Bouza et al., 2006).

TUNA vs TURP.

TUNA was rigorously compared with TURP in an RCT that had data reported at multiple time points. The first installment occurred at 1 year postrandomization and showed that **both procedures were efficacious but with superiority in the TURP cohort** (Bruskewitz et al., 1998). A significant decrease was seen in AUA-SS in both arms at 1 year, with TURP (64% decrease) having a statistical advantage compared with TUNA (55% decrease). Measured prostate volume actually increased in the TUNA group (+2.4%), and the TURP group had a 17% reduction ($P = .014$). Peak urinary flow also underwent a more significant improvement in the TURP group (147.6%) compared with the TUNA group (72.4%), although both groups improved compared with their respective baseline. Longer hospital stay was noted in the TURP group as all patients in the TUNA group went home the day of the procedure.

The second installment focused more primarily on UDS changes noted between the treatment arms (Roehrborn et al., 1999). **Changes in the Abrams-Griffiths number and detrusor pressure at peak flow were superior in the TURP group.** When comparing UDS changes to symptom improvements, they were not able to predict which preprocedural UDS findings could predict postprocedural subjective success.

The final publication from this series occurred after 5 years post-treatment (Hill et al., 2004). Cautious conclusions should be taken from these results as at least one-half of the initial cohort did not provide data at the 5-year mark, and in some categories only 20% of the initial cohort was analyzed. Both treatments were found to be effective in treating BPH, but TURP was superior in almost all metrics. AUA-SS improvements were more profound from years 1 to 4 for TURP. Peak flow was better at all analyzed time points in the TURP group compared with TUNA. TUNA did have less adverse events but a higher need for retreatment (13.8%) compared with 1.8% in TURP group.

Another RCT by Cimentepe et al. (2003) had overall results that were more favorable to TUNA but still not exceeding TURP. The authors reported no postoperative complications in the TUNA group other than a 7% risk for retreatment over 18 months.

The meta-analysis of RCTs (Bouza et al., 2006) **concluded that TUNA and TURP were fairly equivalent in results at 3 months, with TURP providing superior results after that point.** Results for symptom score were improved by a factor of 1.3 at 1 year and 1.49 at 3 years. QoL score had less of a disparity, with a factor difference in results of 1.14 at 1 year and 1.34 at 3 years. **Maximum flow of the TURP group was at least double the improvement seen in the TUNA group throughout the entire analysis.**

Complications.

The excellent systematic review and meta-analysis by Bouza et al. (2006) analyzed the total complication rates of both open and comparative trials. **They found that TUNA had a much higher rate of secondary procedures (OR 7.4) compared with TURP but was safer with a lower rate of complications (OR 0.14).** They noted that differences were particularly notable in risk for sexual disorders and postoperative bleeding.

Intraoperative and Perioperative.

In the study by Steele and Sleep (1997), a mild postprocedural **hematuria** was seen in all 47 patients. At 1 month postprocedure, 8% continued to have some degree of **irritative voiding symptoms. Pain during the procedure** is a fairly common finding, with 22% of patients reporting in one series (Roehrborn et al., 1998b).

Postoperative.

In the comprehensive study by Rosario et al. (1997), patients were routinely sent home with catheters after initial problems with postprocedure retention. Likely as a result of this, they had a high rate of **UTI** (14%). Only 5.8% of patients reported **sexual dysfunction,** although the rigor to which this was investigated in the individual trials is suspect**. Dysuria** was noted in 7% of patients in the review, and other studies reported this as high as 25% (Ramon et al., 1997).

Perineal pain both during and after the procedure is a common finding, with 50% of patients in one study having pain lasting 1 to 2 weeks and 23% using pain medications for control of this pain (Daehlin et al., 2002).

From the comparative trials, Bruskewitz et al. (1998) noted a 12.7% incidence of **ED** in the TURP group, with no TUNA patients reporting ED. A **decrease in ejaculation** was noted in the TURP group 54% of the time, and only 13% of TUNA patients noted the same complaint. At final analysis of this cohort, 41% of the TURP group reported **retrograde ejaculation,** with no TUNA patients reporting this (Hill et al., 2004). **Prolonged catheterization** is unlikely as 90% to 95% of patients have been shown to be catheter free within 1 week of treatment (Chapple et al., 1999).

Conclusion.

The role of TUNA in the continuum of BPH treatments is difficult to ascertain because there is insufficient evidence and a lack of high-quality studies with significant long-term data. Although TUNA statistically improves symptoms, QoL, and urinary flow rates, the results are not as impressive as other treatment options for LUTS/BPH. The reduction in prostate volume is negligible as the cavitated areas are putatively replaced with scar leading to minimal significant change in overall prostate volume. Although a large initial volume of research was generated, there is a paucity of recent publications. Likely this technology is headed toward a minimal role as more durable and impressive options continue to evolve. Although overall the procedure is very safe, it is an overall less attractive as other MIST options.

Transurethral Incision of the Prostate

Introduction and Concept.

A dynamic role of peripheral condensation of the prostatic stroma acting as a capsule leading to BPH/LUTS has been proposed (Hutch and Rambo, 1970; Ohnishi, 1986). The alleviation of symptoms seen in patients with BPH treated with α-blockade also supports this capsular contraction or prostatic hypertonicity leading to symptoms. Clearly, capsular constriction could further exacerbate the symptoms derived from an already hyperplastic prostate.

The practice of incising the prostate or bladder neck to relieve voiding symptoms has been verified as early as reports dating back to the 1800s. In their review, Hedlund and Ek (1985) credit Guthrie in 1834 with the first disruption of the bladder neck as a treatment.

Transurethral incision of the prostate (TUIP) is an operative approach to disrupt the prostatic capsule to alleviate voiding symptoms. This procedure can be considered in men with small prostate glands (<30 g), although surgeons have tried this in larger glands. **Generally, a unilateral or bilateral incision is made through the bladder neck and can be extended all the way distally to the verumontanum. This incision is usually made posterolaterally (in the region of the 5 o'clock and 7 o'clock positions).**

The ideal patient for this procedure is a young man with a small prostate who is concerned about either a loss of ejaculation or future fertility. This procedure has a lower risk for retrograde ejaculation than other BPH treatment options, particularly if only done unilaterally. However, if retrograde ejaculation is truly being avoided, authors have avoided bladder neck and complete capsular incision (Orandi, 1987).

Technique.

The most critical part of the preoperative care for a TUIP is **correct patient selection.** Patients with large glands or significant symptoms are unlikely to achieve significant benefit and will likely require additional treatment. Many studies exclude patients with a median lobe from the procedure, and this should be considered as a potential contraindication. However, other authors have found that the presence of a median lobe is not a contraindication and opine that with incision of the prostate, the median lobe will often become atrophic (Orandi, 1985).

The technique itself is fairly simple and technically straightforward. A cold knife, hot knife, resectoscope with a thin loop, or even end-firing holmium LASER can be used to complete the procedure. The incision should be started distal the ureteral orifice. Incision is carried through the bladder neck, into the prostate with the incision ending proximal to the verumontanum. The depth of incision should visualize the surgical capsule at a minimum, but more aggressive surgeons may prefer to see periprostatic fat as they incise through the capsule. Hemostasis should be achieved, but significant bleeding should not be encountered (Fig. 146.18).

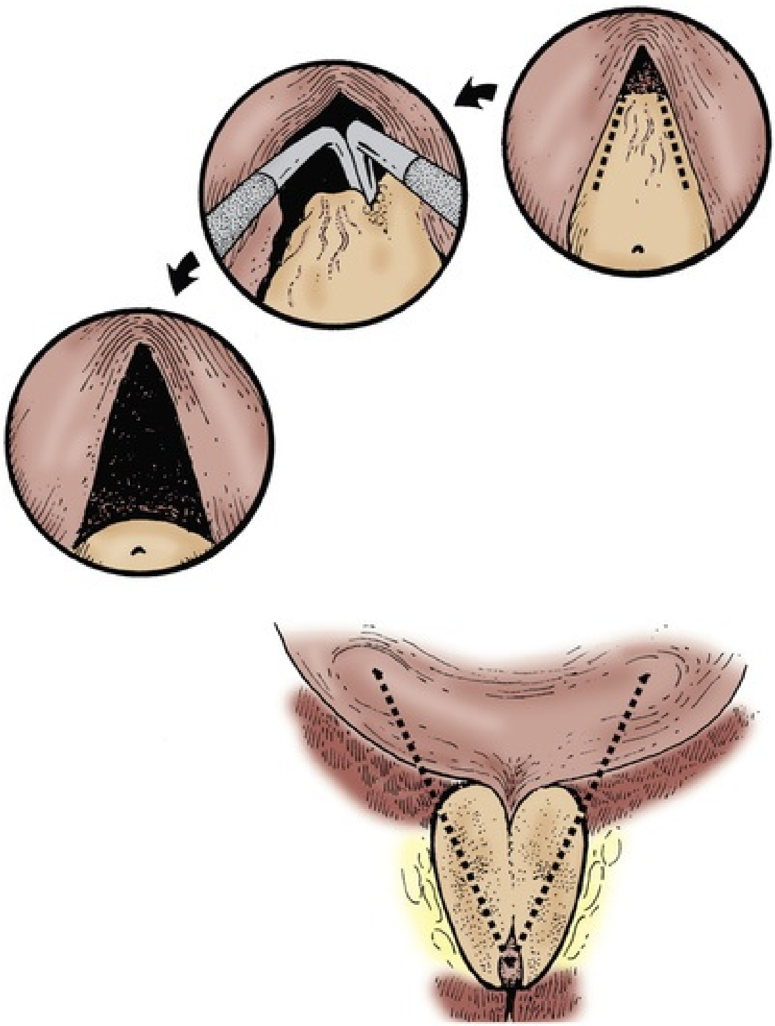

FIG. 146.18 Transurethral incision of the prostate. The incision is started at the ureteral orifice and carried through the bladder neck up to the verumontanum. This procedure is done bilaterally. (From Mebust WK. A review of TURP complications and the National Cooperative Study. Lesson 24, volume 8. *AUA Update Series* 1989:189–190.)

The patient can have the catheter removed and can be discharged to home quickly after surgery (the day of surgery or next day). Convalescence should be rapid with little to no postoperative irritative symptoms.

Outcomes

Single-Cohort Studies.

Compared with other BPH treatments, TUIP has generated less significant and rigorous research. Only a few large series exist, and they are primarily focused on few authors. In a rigorous study by Sirls et al. (1993), a small group of patients were evaluated with both subjective and objective measures to evaluate the procedure. UDS were routinely performed along with interviews and questionnaire data in 41 patients. Data was only reported if patients were followed for a minimum of 12 months. Significant changes were seen in mean peak urinary flow (increased from 10 to 15 mL/sec) and Madsen-Iversen symptom scores (decreased from 12.5 to 6.9). The mean detrusor pressure at maximum flow decreased (from 85 to 44 cm of water), which was statistically significant, but left many patients remaining in the obstructed (29%) or equivocal (43%) classification by the Abrams-Griffiths nomogram. Additional subjective information was obtained by interview. Although no objective questionnaire was used to evaluate sexual function, only 11% of patients reported new retrograde ejaculation. Additionally, only 67% of patients reported being overall satisfied with the procedure.

In the large series published by Orandi (1990), 646 cases over a 15-year period were assessed. Although not randomized, many patients during that time underwent TURP, and some matching of results was attempted.

Comparative Studies

TUIP vs TURP.

The trials comparing TUIP and TURP are of generally poor methodological quality with nonuniformity making any large meta-analysis prohibitive. Specifics on randomization are most notably missing. Additionally, they sample a fairly homogeneous group of patients with small prostates.

In a randomized study of 85 subjects by Jahnson et al. (1998), the authors evaluated patient prostate volume primarily with DRE (TRUS in some circumstances). In those evaluated by TRUS, the average prostate volume was less than 27 g in both groups. The authors concluded that operative time was longer in TURP compared with TUIP; furthermore, TURP subjects experienced a greater estimated blood loss (EBL) but larger improvement in postoperative Qmax. Ten patients in the TUIP group required reoperation compared with only three in the TURP group ($P = .039$).

Another randomized study by Tkocz and Prajsner (2002) only included patients with a prostate volume less than 30 g by TRUS. The age range of patients included was 51 to 78 years, and assessment was made at 24 months. Although both groups had statistical improvements in AUASS, Pdet at Qmax, and Qmax, there was no significant difference between groups in these metrics.

Retrograde ejaculation was seen in only 12% of the TUIP group, compared with 32% of the TURP group, although it was unclear if this was statistically different.

Soonawalla and Pardanani (1992) published the largest randomized series, which excluded patients with glands larger than 30 g. Although patients were randomized to either TURP (*n* = 110) or TUIP (*n* = 110), the TUIP group did have a small volume of prostate resected for histopathologic examination. A surprising number of patients (38 of 110) having a TURP received a blood transfusion. Peak flow rates were increased in both the TURP (157%) and TUIP (145%) groups.

Lourenco et al. (2010)**published a fairly recent analysis of randomized trials involving TUIP. The authors concluded that the available randomized trials were of "poor to moderate quality," and in many comparisons only a few trials could be included because the trial did not report methods or results comprehensively enough. TURP had a more significant improvement in flow rates, and a conclusion on changes in symptom scores could not be drawn from the data.**

Complications

Intraoperative and Perioperative.

Hemorrhage should be controlled quickly, although significant bleeding and transfusion are rare. In cases in which **capsular perforation** occurs (either intentionally as part of the procedure or caused by an overly zealous incision), this can generally be treated with prolonged postoperative catheterization. In the series by Orandi (1985), 11% of patients had temporary **urinary retention** after TUIP. Significant hemorrhage was rare, with only 0.9% of patients requiring **transfusion.** The previously discussed analysis of RCTs (Lourenco et al., 2010) more confidently reported morbidity data. A higher rate of **blood transfusion** was found in TURP but was fueled by two studies, with abnormally high rates of 35% (Soonawalla and Pardanani, 1992) and 80% (Nielsen, 1988).

Postoperative.

Retrograde ejaculation is less likely with TUIP than with other forms of BPH treatment. Reported rates of retrograde ejaculation range from 0% to 37% but are likely toward the lower end of this range. The incidence of this complication is less likely with one incision (Turner-Warwick, 1979), but other reports came to the conclusion that two incisions did not increase the risk (Hedlund and Ek, 1985). When compared with TURP, TUIP had a lower risk for retrograde ejaculation (RR 0.54, *P* < .001) but a higher risk for reoperation (RR 2.40, *P* < .01). The risk for **ED** with either treatment was not different. Additionally, they found no difference between treatments with respect to urinary retention, urinary infection, stricture, or incontinence (Lourenco et al., 2010). In the Orandi series (1987), 2.9% of patients developed urethral stricture, and 9.6% required repeat prostatic surgery. In fewer than 1% of cases were complications of incontinence or bladder neck contracture encountered.

Summary.

TUIP offers reasonable results in correctly selected patients. It does appear to have a lower risk for retrograde ejaculation compared with other treatment options, particularly TURP. The operation is of short duration, and a minimal hospital stay is required. This treatment should be discouraged in a patient with a larger prostate gland but may be of benefit in patients who are particularly concerned about retrograde ejaculation.

Key Points

- M-TURP is still an important treatment for LUTS/BPH but will continue to progress to B-TURP because of multiple improvements in its safety profile.
- MIST treatments like TUNA and TUMT have been plagued by a high need for retreatment and likely fill a role between medical management and more invasive and effective treatments for LUTS/BPH.
- TUIP is a reasonable treatment option in the carefully selected patient.

LASER Treatments

LASER treatment of BPH has been an increasing choice for urologists and patients. Over the past decade, LASER technology has become more refined, leading to improved treatments and outcomes. The acronym LASER stands for “light amplification by stimulated emission radiation.” **LASER prostate treatments rely on the prostate interacting with the light energy and converting it to local thermal energy.** The volume of tissue that is heated by the LASER depends on multiple variables, including light scatter, reflection, and most importantly absorption.

Initial LASER technologies relied on tissue coagulation with eventual abandonment in favor of LASERs with a preference for vaporization. The temperature that the tissue is heated to determines whether the tissue is vaporized or coagulated. Below the vaporization temperature, the tissue proteins are denatured, leading to coagulative necrosis with delayed tissue death and sloughing. Vaporization occurs when the tissue is heated above the vaporization (boiling) temperature, which leads to intracellular water vaporization and quick tissue destruction.

The amount of tissue that heats beyond a target temperature during LASER treatment of the prostate is based on characteristics of the LASER and tissue. LASER characteristics include the irradiation time and power along with delivery characteristics such as power intensity, beam angle, and spread. Tissue variables such as carbonization and light scatter affect tissue heating also and the response to the applied energy. An appeal of the LASER technologies is the ability to allow for ambulatory or outpatient surgery or mimic a more invasive treatment option with a minimally invasive approach (e.g., holmium enucleation replacing OP).

There are several characteristics of LASERs that we will discuss briefly. The wavelength of the LASER is the distance between the sinusoidal waves of the LASER energy and is measured in nanometers. Energy of a LASER is measured in Joules and is the amount of work or heat that the LASER produces. The LASER power is measure in Watts and is the amount of energy that the LASER produces in a certain amount of time.

LASER Safety.

The incorporation of LASER energy into the operating room has allowed for many new techniques for the treatment of BPH along with multiple other urologic and nonurologic indications. The ability to destroy tissue is important for prostate treatment but when used errantly can lead to unintended consequences such as injury of the patient or operating room personnel. In particular, the human eye is at the highest risk for accidental exposure because of the lack of a protective layer (like the epidermis for most of the body).

The portion of the eye that is injured depends on the wavelength used. For LASERs with a larger wavelength like the holmium or thulium, the cornea is at greatest risk. The potassium-titnyl-phosphate (KTP), lithium-triborate (LBO), and neodinium:yttrium-aluminum-garnet (Nd:YAG) LASERs are particularly dangerous as this wavelength is focused on the retina. The lens of the eye focuses this energy on the retina causing an increased intensity of up to a factor of 100,000 (Donnell, 2014).

The regulation of the operating environment is standardized by the Occupational Safety and Health Administration (OSHA). **LASERs are classified by their inherent wavelength, maximum output power, and risk for damaging the eye or skin.** All of the LASERs used by urologists are class 4 LASERs (the highest classification) and can cause permanent eye damage from a variety of exposures including indirect beam contact.

The safe use of LASERs in surgery should be done as part of a “**culture of safety.**” Appropriate OSHA-approved signage should be displayed outside the room so that personnel entering the room are aware of the use of LASERs. Appropriate LASER-rated protective eyewear should be worn by all persons in the operating room (including the patient) and should be accessible to those entering the room. Any windows or other portals for LASER light to leave the operating room should be appropriately blocked to prevent the escape of LASER light.

The LASER technician or surgeon should review the LASER before each case to inspect for any visible signs of damage, and all LASER operators should have received appropriate training. Your institution likely has a LASER safety officer who can be consulted with any questions regarding LASER usage or safety.

Holmium and Prostate Enucleation

Introduction and Concept.

The Ho:YAG LASER emits light at 2140 nm but has a pulsed instead of continuous energy emission. This wavelength is strongly absorbed by water (and water-rich tissues) and has an absorption length of 0.4 mm with excellent hemostatic properties (Kuntz, 2006). The light is easily transmitted along flexible quartz fibers and creates a high-energy density that leads to vaporization with a superficial coagulation zone. The dissipated heat from the tissue-fiber interaction is dissipated over a short distance (2 to 3 mm) and causes coagulation of small- to medium-sized vessels.

Although this LASER has many uses in urology, it is generally now used to precisely incise tissue when used for BPH treatment. Historically, the holmium LASER was used also for ablative procedure (HoLAP), but its hemostatic properties were found wanting when compared with other contemporary LASER technologies. **Primarily it is now used to enucleate the prostate in a procedure named the holmium LASER enucleation of the prostate (HoLEP).** This procedure allows the surgeon to follow anatomic planes to enucleate entire lobes of the prostate. Generally, these lobes are then pushed into the prostate with subsequent morcellation.

Holmium resection of the prostate (HoLRP) was the precursor procedure to HoLEP. In HoLRP, large sections of the prostate were cut away and pushed into the bladder for later retrieval. **However, with the incorporation of morcellation, the pieces resected could be larger (now entire lobes), and the HoLRP fell out of favor for the more efficient HoLEP**.

LASER enucleation represents the endoscopic response to open simple prostatectomy and is the most technically advanced LASER prostate surgery. Many reviews and meta-analyses of the HoLEP make this the most rigorously analyzed LASER technique (Gravas et al., 2011).

Although a treatment with excellent results, a difficult and exaggerated learning curve has consistently been seen in adapters of this technique. Although the enucleation of lobes is not without possible complication, the morcellator requirement can lead to significant injury to the urinary bladder with catastrophic complications (e.g., bladder fibrosis, cystectomy, and need for urinary diversion).

Technique

Preoperative.

This technique is probably not necessary for small glands (with many alternatives available) and may be better suited for patients with a larger gland that would previously have received an OP.

Although crossmatching of blood may not be necessary as a routine precaution for this procedure, the urologist may be well headed to consider a preoperative crossmatch for blood transfusion. Antibiotics should be administered as described earlier for TURP. HoLEP generally is done in a hospital (or outpatient surgery center) under regional or general anesthesia. Patients should be counseled that an overnight stay is expected with catheter removal the next day.

Intraoperative.

The HoLRP and current HoLEP technology both utilize the Ho:YAG LASER generator. This technology uses an end-firing 550-micron fiber delivered through a continuous-flow LASER resectoscope (usually 26 Fr in size). The LASER resectoscope has a modification in which the inner sheath contains a fiber guide to stabilize and prevent fiber movement while in use. A 6-Fr open-ended catheter may also be used as a fiber guide when placed through the sheath. An offset lens of 30 degrees is used along with normal saline irrigation (▶Video 146.1).

The HoLEP technique was initially described by the group from New Zealand led by Gilling (Fraundorfer and Gilling, 1998). The use of the morcellator modified the technique from the HoLRP to the HoLEP. Initially, the size of the pieces that could be removed from the prostate was limited to a size that was small enough to be retrieved through the modified resectoscope. With the addition of morcellation, larger pieces were able to be fragmented and removed, making enucleation possible. These whole prostate lobes were moved into the bladder after enucleation with morcellation then commencing after the entire enucleation was complete.

An 80-W or 100-W generator is used. The power settings are generally 2.0 J at 50 Hz, giving the surgeon a total of 100 W. **The procedure begins with a bladder neck incision at the 5 o'clock and 7 o'clock positions.** These incisions are carried down to the surgical capsule, which is identified by its reflective fibers running longitudinally. This is an important distinction as the landmark will mark the depth for the remainder of the procedure. **The incisions are lengthened distally until just proximal to the verumontanum.** Incisions are widened laterally by following the surgical capsule to undermine the lateral lobes. This allows for improved visualization with a larger channel of irrigation influx to the bladder and sets up later steps in the case.

A transversely oriented incision is made between the distal aspects of the previously extended bladder neck incisions. This begins the undermining of the median lobe in a retrograde fashion. **The surgical capsule is followed as the median lobe is lifted off the capsule.** The beak of the scope may be used to retract the median lobe to improve visualization. This step is complete once the median lobe has been enucleated and advanced into the bladder. Care should be taken to not undermine the bladder during the latter portion of this step.

The incisions made at the distal aspects of the lateral lobes are now developed to enucleate the lateral lobes. These incisions are developed laterally up the walls once again following the surgical capsule. Initially, this is done circumferentially at the apex of the prostate and then carried proximally toward the bladder neck, separating the adenoma from the capsule. An incision at the 12 o'clock position is then made down to the capsule. The surgical capsule is then followed from both the inferior and 12 o'clock position until the entire lobe is free and can be moved into the bladder. The procedure is repeated on the other side, and hemostasis is achieved using a defocused LASER beam to coagulate any bleeding.

Morcellation is then used to remove the large adenoma pieces from the bladder as the morcellator digests these large pieces down to more manageable strips of tissue. A dedicated scope or nephroscope with a 5-mm working channel is used. The morcellator itself has two blades within a long hollow inner lumen. The bladder is distended to keep the bladder wall away from the morcellator's moving pieces. A foot-operated variable suction is applied to the morcellator to draw the adenoma pieces toward the morcellator. Once the pieces are engaged, the morcellator's guillotine action slices off fragments of tissue. These smaller fragments are able to be suctioned through the lumen of the morcellator. A unique complication of the morcellator is bladder injury, and the operator should be careful to stop suctioning if the blade engages the bladder mucosa. Small, residual fragments may be removed with the flow of irrigation through a resectoscope sheath or with a large-bore syringe.

An alternate technique of lobe fragmentation or “mushroom” technique involves leaving the lobes attached at a stalk and then resecting the lobes down into pieces suitable to come through the resectoscope (Hochreiter et al., 2002). A urethral catheter is then carefully placed after all of the fragments have been removed. Of course, this technique allows for preservation of the tissue for histologic examination, and the morcellated pieces should be sent to the pathologist for examination. Additional hybrid holmium resection/enucleation techniques have been described that improve the learning curve and have decreased complication rates compared with traditional HoLEP (Helfand et al., 2010).

Postoperative.

A minimum of an overnight hospital stay is generally accepted, and patients can expect to be discharged on the first postoperative day. In the absence of a definitive capsular perforation, the catheter can be removed first thing in the morning. If a large perforation has occurred, the catheter should be left for a few days and then removed at the clinic without further repercussions.

Although most bladder injuries during morcellation are superficial and require no additional treatment, large extraperitoneal or intraperitoneal bladder injuries may require exploration and closure. Unless there is a large degree of extravasation of irrigant from an extraperitoneal injury, these can generally be managed conservatively with extended catheterization.

Outcomes

Single-Cohort Series.

Large series of patients appeared quickly, and one of the early adapters reported on 552 patients retrospectively in 2005. **Elzayat et al.** (2005a)**found a 200% increase in Qmax to complement a 75% improvement in AUA-SS at 1 year.** A short mean catheterization (1.4 days) and hospital stay (1.5 days) was also observed. **The authors quickly reported on successful treatment of large glands customarily removing over 100 g at surgery** (Moody and Lingeman, 2001)**. The ability to handle such large glands quickly made this a unique endoscopic treatment, as most other technologies did not include gland sizes larger than 70 to 80 g in studies.** Studies looking at patients in AUR displayed the effectiveness of the treatment. In a study of patients with a mean volume of 670 mL of urine drained at initial catheter placement, only 1.75% of patients were unable to void after surgery (Elzayat et al., 2005b). In another study on patients with urinary retention, all patients were able to void after surgery (Peterson et al., 2005).

Longer-term data continued to be encouraging. In a review of 118 cases by Elzayat and Elhilali (2007), objective data were only available on 26 patients at 6 years, but mean flow increased from 6.3 to 16.2 mL/sec and mean AUA-SS decreased from 17.3 to 5.6 ($P < .0001$ for both). They observed that 8% of their first 50 cases required retreatment with only 1.5% of the later 68 patients requiring retreatment, hinting that a significant learning curve may be expected. Enucleated tissue weight and total energy used were increased in the latter group, possibly explaining the lower retreatment needs.

Krambeck et al. (2010a) reported on their data from 1065 HoLEP patients. Although they had a mean follow-up of 287 days, (range 6 to 3571 days), they observed an increasing maximum flow and decreasing AUASS when stratifying patients by time from procedure. This further solidified the long-term efficacy of the procedure.

The popularity of the HoLEP has been hampered by concerns about a steep learning curve. This was evident in the analysis of the first 125 patients undergoing the procedure by a self-taught surgeon (Placer et al., 2009). **In skilled hands, the HoLEP can treat glands over 175 g with a reported outcome equivalent to OP with a low morbidity** (Krambeck et al., 2010b)**, but it has been estimated that a self-taught trainee must perform at least 20 procedures on moderate-sized glands before being able to reliably reproduce quality results** (El-Hakim and Elhilali, 2002).

An advantage of the HoLEP technique is that it appears that prostate size does not influence efficacy in a surgeon with experience in this technique. When researchers broke down prostate size into three groups with increasing size, they found that although mean resected tissue weight increased among groups, the groups all had immediate and profound changes in AUASS, flow rate, and residual volume. Complication rates were roughly equivalent, with only a slight increase in bleeding noted with increasing prostate size (Kuntz et al., 2004a).

Comparative Series

HoLEP vs. TURP.

A large RCT looking at HoLEP versus M-TURP was initially composed of 200 urodynamically obstructed patients who were randomized to HoLEP or M-TURP. Prostate volumes were measured by TRUS to be approximately 50 g in both groups, and patients had high PVRs (>200 mL) in both groups. Follow-up was available out to 36 months; results were published in two reports.

The authors reported a significantly decreased change in hemoglobin (1.3 vs. 1.8 g/dL), catheterization time (27.6 vs. 43.4 hours), and hospital stay (53.3 vs. 85.8 hours) in an initial report (Kuntz et al., 2004b). Operative time was longer in the HoLEP group (94.6 vs. 73.8 minutes). Peak flow rates improved from 4.9 to 23.1 mL/sec in the HoLEP group, with the TURP group improving from 5.9 to 25.5 mL/sec at 12 months without differences seen between groups. Residual volume in the HoLEP group was superior compared with the TURP group (4.8 vs. 16.7 mL at 6 months and 5.3 vs. 26.6 mL at 12 months), although with such low volumes this is likely not clinically significant. AUA-SS were in the low 20s in both groups preoperatively to 4.3 (HoLEP) and 5.5 (TURP) at 1 month.

At 36 months, PVR continued to be significantly lower in the HoLEP group (202 mL vs. 8.4 mL). The statistical difference between AUASS was no longer present, but both groups had a very low score (2.7 in HoLEP, 3.3 in TURP). Flow rates were not different between groups and were greater than 27 mL/sec in both groups (Ahyai et al., 2007). Other RCTs have verified the increased operative time with decreased catheterization and hospital time (Montorsi et al., 2004; Tan et al., 2003).

The longest randomized data comparing HoLEP to TURP come from Gilling et al. (2012) and includes 7-year follow-up of 31 of the initial 61 subjects. Data from the initial operation was reviewed and is in agreement with the increased operating room time and prostate tissue weight removal. Catheterization (17.7 vs. 44.9 hours) and hospital time (27.6 vs. 49.9 hours) were once again lower for HoLEP versus TURP. They concluded that HoLEP is at least equivalent to TURP with regard to durability. In their data, three of the TURP patients required additional intervention for BPH (compared with none in the HoLEP group).

Multiple meta-analyses have been performed looking at RCTs of HoLEP versus TURP Lourenco et al. found increased rates of Qmax for HoLEP compared with TURP (weighted mean difference of 1.48 mL/sec) (Lourenco et al., 2008). Symptom scores trended toward an advantage for HoLEP but did not quite meet statistical significance. Lourenco et al. and another meta-analysis (Tan et al., 2007) found shorter catheter and hospital times. With different RCTs included in their reviews, the analysis of flow rates did not meet statistical significance in the latter review.

The most convincing data for HoLEP utility was published in the meta-analysis of RCTs by Ahyai et al. (Ahyai et al. 2010). **The authors concluded that operating room time was indeed increased, but because of the large weight of adenoma removed in studies, HoLEP and TURP have similar time efficiency (weight of adenoma removed/operating room time).** Catheter time was also found to be shorter in the HoLEP group. **Most interestingly, statistical superiority in support of HoLEP was seen with regard to change in AUASS and Qmax. The authors concluded that HoLEP was the only endoscopic procedure that has shown superiority compared with TURP.** For longer-term data, Cornu et al. (2015) analyzed results after 3 to 8 years postprocedure. Although data could only be reliably drawn from the two studies in the analysis, results still appear to favor HoLEP.

HoLEP vs. Open Prostatectomy.

HoLEP is effective in treating BPH, particularly in large glands, and has fared well in two randomized trials comparing HoLEP versus OP. Naspro et al. (2006) randomized 80 consecutive patients with a prostate size greater than 70 g to HoLEP (mean prostate size 113 g) or OP (mean prostate size 124 g). The authors reported a decrease in time to catheter removal (4.1 vs. 1.5 days), length of stay

(5.4 vs. 2.7 days), and risk for blood transfusion (7 vs. 2 patients) for subjects in the HoLEP group. Subjects in the OP group had a shorter mean operative time (72 vs. 58 minutes) and greater amount of adenoma removed (87.9 vs. 59.3 g).

Patients underwent repeat urodynamic assessment at 12 months, with uroflow and AUA-SS assessment out to 24 months. Comparable urodynamic improvements were seen in both groups. Qmax improved significantly in both groups, from a baseline of 7.8 and 8.32 mL/sec to 19.19 and 20.11 mL/sec at 24 months, for the HoLEP and OP groups, respectively. **Between groups, there was no statistical difference in voiding rates at any time.** Both groups also experienced a statistically significant improvement in AUASS from 20.11 and 21.60 to 7.9 and 8.1 at 24 months for the HoLEP and OP groups, respectively. **There was no statistical difference at any time point in AUASS between groups.**

Five-year data from Kuntz et al. (2008) demonstrates excellent durability in improvements in AUASS, Qmax, and PVR in their study of 120 subjects with large prostate glands (>100 g) who were randomized to HoLEP or OP. AUASS improved by nearly 19 points in both groups at 1 year, and was sustained out to 5 years. Although operative time was longer in the HoLEP group, no patients required a blood transfusion (compared with 13% in the OP group), length of stay was shorter, and catheterization time was shorter. **At 5 years, both HoLEP and OP groups experienced significant improvements in AUASS, Qmax, and PVR, with no differences observed between groups.** Bladder neck contractures and urethral strictures were noted in both groups, but there was no statistical difference in likelihood of a delayed complication or required intervention for complication.

HoLEP in the Anticoagulated Patient.

The data regarding the use of HoLEP in the setting of anticoagulation are based entirely on small retrospective cohorts of subjects on a variety of anticoagulation or antiplatelet therapy. Data regarding the continued use of oral anticoagulation or antiplatelet therapy at the time of surgery are sparse, as the majority of the literature has focused on patients who discontinued their medication in the perioperative period. The largest series available was recently published by El Tayeb et al. (2016), which compared 116 patients on anticoagulation or antiplatelet therapy to 1558 control patients. They reported longer length of stay (27.8 vs. 24 hours), duration of continuous bladder irrigation (15 vs. 13.5 hours), and increased risk for reoperation rate (1.9 vs. 0.7%). Further subgroup analysis also revealed an increased risk for blood transfusion for patients in whom anticoagulation could not be stopped at the time of surgery (6.7 vs. 2.32%).

Several other retrospective reviews have demonstrated similar findings. There does not appear to be an increased risk for longer operative or morcellation time (Bishop et al., 2013, El Tayeb et al., 2016). Blood transfusion rate, length of stay, and time to successful void trial do appear to be increased in patients on anticoagulation, although there are conflicting data among these heterogeneous reports (Bishop et al., 2013; Neuville et al., 2018; Tyson and Lerner, 2009). Patients should be counseled appropriately about these risks, yet surgical outcomes appear to be similar to men not on anticoagulation. Lastly, the literature regarding newer direct oral anticoagulants and HoLEP is limited, so further studies are needed before drawing any conclusions regarding these newer agents.

Complications

Intraoperative and Perioperative.

Although the use of the morcellator has led to decreased operative times compared with HoLRP (Gilling et al., 1998), it does enable a unique complication in that **morcellator-mediated bladder injury can occur.** Although these injuries are generally superficial, the possibility of deeper and more significant injury is certainly possible as the morcellator engages tissue indiscriminately. Keeping a reasonable volume of irrigant in the bladder and a bloodless field may help visualization and reduce this risk. Reported ranges of these injuries vary widely, with one study reporting an 18.2% occurrence (Montorsi et al., 2004).

Another unique complication is the possibility of **incomplete evacuation of the adenoma** leading to postponed morcellation. This is generally caused by a malfunction of the morcellating device or poor hemostasis leading to obscured vision.

During either enucleation or morcellation, there is the possibility of **injury to the ureteral orifice.** This outcome was only examined in a few series. One report found a 2.1% chance of occurrence (Shah et al., 2007), and another series found that of the four of these injuries that occurred, three were in the group with the largest prostates (>80 g) (Kuntz et al., 2004a).

Capsular perforation generally occurs as the resection is carried along in the plane between the prostate adenoma and the surgical capsule. Although carrying into the adenoma in this area will cause bleeding, an error to the other side will lead to capsular perforation. Many authors classify these perforations into categories including “threatened,” “covered,” or “free” and use the degree of perforation to guide management. Generally, authors have managed complete or “free” capsular perforation with prolonged catheterization (a few days) with no change in management for other types of perforation. This complication has been reported as high as 9.6% (Shah et al., 2007), with another large review placing this complication lower at 1.5% (Kuo et al., 2003).

The overall risk for **hemorrhage** during HoLEP is fairly minimal. A defocused holmium LASER beam can be used to control most bleeding, and conversion to another form of transurethral intervention is a rare to never event. It does appear that the risk for bleeding increases with increasing gland size, although the correlation was fairly weak (Kuntz et al., 2004a).

Bleeding is also well controlled by the hemostatic properties of the holmium LASER. Some series have reported a **transfusion rate** as high as 1.7% after HoLEP (Shah et al., 2007), but data incorporated into the meta-analysis of Lourenco et al. (2008) found that HoLEP had a decreased relative risk for transfusion compared with TURP (RR = 0.27).

Postoperative.

Urinary urgency and other storage symptoms are a common finding after HoLEP and are thought to be caused by the high amount of LASER energy applied to the capsule during enucleation (Shah et al., 2007). In attempts to grade the severity of these symptoms, Larner et al. (2003) found that most patients characterized the symptoms as mild (defined as causing minimal bother).

Transient urinary incontinence occurs with some frequency but generally resolves with time. In the study by Shah et al. (2007), 10.7% of patients reported initial incontinence, with only 0.7% of the cohort maintaining this complaint permanently. A similar pattern was seen in another large study, in which 4.2% initially reported stress-type incontinence, but only 0.5% had this complaint at the last visit before publication (Elzayat et al., 2005a). This may be avoided by careful incision at the 12 o'clock position with care to not incise distal to the verumontanum. The depth and length of the required incision may be mistaken by a more novice surgeon (Shah et al., 2007).

The incidence of **bladder neck contracture** is 0% to 3.2% (Shah et al., 2007) and appears to occur more likely in smaller prostates (Kuo et al., 2003). The surgeon may consider a prophylactic bladder neck incision in patients they deem at a higher risk for this complication.

Urethral stricture is a common finding, with studies reporting an incidence as high as 7% (Seki et al., 2003) and a later meta-analysis finding a rate of 4.4% (Ahyai et al., 2010). The large-diameter instruments used during the procedure may predispose to this occurrence. Although the location of the stricture was not frequently reported, one group found this to occur more frequently at the meatus (Seki et al., 2003).

Retrograde ejaculation is a common finding after HoLEP, with two randomized trials finding incidence rates of 75% and 78% (Briganti et al., 2006; Wilson et al., 2006). However, one of these trials found that changes in IIEF domains were minimal (Briganti et al., 2006).

Conclusion.

HoLEP is an interesting treatment option overall. Although there are concerns about an exaggerated learning curve, results are comparable if not superior to TURP. Patients have significantly decreased catheterization and hospital times. Although the time in the operating room is increased compared with TURP, many studies show equivalent efficiencies in tissue removal, offsetting the increased operating room time. Additionally, it appears that reintervention rates for BPH may be lower. Complication profiles show HoLEP, with a lower rate of transfusion and similar rates of bladder neck contracture and urethral stricture to TURP.

Prostate Ablation and Vaporization

Concept and Introduction.

The KTP and LBO labeled LASERs are a derivative of the Nd:YAG. The 1064-nm wavelength Nd:YAG LASER beam is passed through a KTP or LBO crystal that doubles the frequency of the light along with decreasing the wavelength to the desired 532 nm. **This wavelength is selectively absorbed by hemoglobin, which acts as an intravascular target for the light energy.** The improved energy density compared with the Nd:YAG LASER led to preferential vaporization, with the hemoglobin absorption improving hemostasis as a thin (0.2-mm) layer of coagulation would be created outside the area of vaporization. The LASER energy freely moves through irrigating fluid without a loss of power.

The original KTP LASER (Greenlight PVP, Boston Scientific Corp., Marlborough, MA) used a 532-nm wavelength and was available in 80-W and 100-W settings. The LBO LASER (Greenlight HPS and XPS, Boston Scientific Corp.) also uses a 532-nm wavelength like the KTP. This LASER offered higher energy setting with an available 120-W (HPS) and 180-W (XPS) setting. This 180-W setting allows for more efficacy in vaporization and coagulation over the 120-W platform (Malek et al., 2011). The 180-W fiber (MoXy Fiber) also has improvements with a built-in dedicated water cooling system for the fiber with automatic safety system that protects the fiber from overheating.

Although the Nd:YAG was originally thought to be the ideal LASER fiber for treatment of BPH (Anson et al., 1993)**, the large amount of prostate sloughing that occurred after visual LASER ablation of the prostate (VLAP) caused by extreme depth of LASER penetration was later found to be undesirable.** The delayed bulk prostate sloughing would often lead patients to suffer from intermittent voiding and urinary retention postoperatively. The failure to sufficiently vaporize tissue was evident in an in vivo canine study (Kabalin et al., 1995).

The VLAP generally utilized a longer-wavelength LASER than the currently used KTP/LBO but is technically similar to the current technique. As the power of the LASER improved, the term *ablation* gradually migrated to *vaporization* because of the immediate removal of tissue visualized during surgery as opposed to the delayed sloughing of tissue seen when called *ablation*. An early canine study comparing the Nd:YAG to the KTP LASER displayed the advantages of a

LASER system that favored vaporization over ablation/coagulation. In this small study, **KTP had significant increases in defect size in the prostates leaving a thin but effective layer of coagulated tissue** (Kuntzman et al., 1996)**. Unsurprisingly, as the power of the LASER has been increased, there have been corresponding improvements in the tissue vaporization** (Kang et al., 2008; Malek et al., 2011; Rieken et al., 2013).

The advantage of the current PVP technology is the combined vaporization and coagulation. Although tissue volume is decreased by the vaporization, coagulation leads to almost instantaneous hemostasis, with closure of venous sinuses reducing absorption of irrigation fluid.

Technique

Preoperative.

A standard preoperative workup should be completed for PVP. Routine cystoscopy is not necessary unless there is particular concern of the patient or physician. Concurrent infection should be ruled out and treated before the operation. Many physicians advocate the use of TRUS to determine prostate size and anatomy. TRUS findings may help the physician to determine if a different surgical approach or technique would be preferable based on the prostatic size or shape. The knowledge of gland size also allows the physician to know the rough estimate of operative time to allow appropriate operating room scheduling.

Patients taking anticoagulation can be managed in many ways before this procedure. It is our preference to allow patients who are already on low-dose aspirin to continue this medication through the operative period with a strong preference for holding stronger aspirin products or other antiplatelet medications. However, we prefer that patients on anticoagulants (e.g., warfarin, apixaban) hold these medications for surgery with the decision on the need for bridging left to the managing physician.

Intraoperative.

The PVP fiber is a 600-micron side-firing probe with the energy produced by the fiber at a 70-degree angle from the longitudinal axis. **Vaporization occurs by sweeping the fiber along the prostate parenchyma, sequentially vaporizing layers of the prostate from the inside out.** Vaporization of the prostate parenchyma is complete when the capsule fibers are visible. **The distance between the LASER fiber and prostate tissue (working distance) is**

important for many reasons and is often difficult to control for the vaporization novice. A distance too close to the tissue will lead to possible “contact vaporization” with resulting damage to the LASER fiber. A distance too far will lead to inefficient energy use with more tissue coagulation (and a subsequent increase in postoperative storage symptoms). If in tight quarters, like at the beginning of the case when the lateral lobes may still be in contact, lower power should be used. Tissue buildup on the fiber should be avoided as this leads to fiber degradation and possibly leading to shortened fiber life and further inefficiencies.

Management of the bladder neck is an important part of the procedure and is generally the first step. We prefer to use a lower-power setting (80 W) in this area. **The ureteral orifices should clearly be identified before beginning treatment of the bladder neck. A single midline incision of the prostate or two incisions at 5 o'clock and 7 o'clock allow for the bladder neck to open. The posterior bladder neck is then vaporized until level with the trigone of the bladder.** After this is complete, the LASER fiber should be pointed in a medial or lateral direction as this allows for visualization of the vaporization that is often lost when working with the fiber pointed posteriorly (toward the rectum). Any potential injury to the ureteral orifices should be minimized by orienting the LASER beam laterally and not pointing in the direction of the ipsilateral or contralateral ureteral orifice. Aggressive coagulation at the bladder neck should be avoided, and we customarily do not vaporize the anterior portion of the prostate in this area to leave a strip of intact urothelium to prevent circumferential vaporization and possible bladder neck contracture. In patients concerned about retrograde ejaculation, incision of the bladder neck fibers can be avoided.

The posterior aspect of the prostate is generally more challenging with PVP compared with TURP as the angle of the PVP fiber does not allow for treatment of tissue directly in line with laser fiber. This can become a more significant problem, particularly in very large prostates where a high bladder neck dominates the visual field. When vaporizing this posterior prostate tissue, we recommend applying LASER energy once again in a horizontal fashion and vaporizing away “layers” of this posterior tissue, carefully working into deeper portions of the prostate parenchyma and not directing LASER energy in a posterior direction (i.e., toward the rectum).

Movement of the fiber into position for vaporization should be done preferentially with a minimization of cystoscopic motion. **A continuous, even**

motion of the sweeping action of the fiber is vital to minimize large and irregular crater formation in the prostate. Bleeding in a recessed portion of the prostate has the potential to be a significant problem as the vessels are unable to be visualized. **The angle of sweep and time to complete the sweep arc are important factors for optimizing outcomes.** If the angle is changed too rapidly, insufficient energy will be transferred, leading to poor vaporization. However, if the LASER beam is left on tissue for too long of a time (slow sweep), a crater will be formed as the energy accumulates in one area. The sweep angle that the fiber is turned at is also an important factor. Research from an in vitro study found that most efficient vaporization occurred when the angle was between 15 and 30 degrees with the depth of coagulation minimized at 30 degrees of sweep (Ko et al., 2012). A frequent rule dictated to the novice vaporizer is to sweep over 30 degrees in 1 to 2 seconds (Welliver et al., 2017).

Bleeding is more frequently seen at that prostate apex, median lobe, and bladder neck, particularly at the posterolateral aspects, where the blood supply of the prostate enters. If bleeding is not severe, the LASER treatment may proceed with focus on the areas directly adjacent to the bleeding area as this may allow for control of the feeding vessels. If pulsatile, arterial bleeding is recognized, the coagulation mode on the LASER may be used. This should once again be used on the area around the bleeding along with the bleeding area itself. If bleeding cannot be controlled, a bugbee electrode may be placed through the working bridge. This allows for the placement of pressure on the vessel to stop continued bleeding (improving visualization) and then controlled coagulation. The surgeon should keep in mind that the irrigating fluid will likely have to be changed to something non-ionic. If all else fails, a larger sheath and possibly the resecting loop should be inserted to help control bleeding. Such need is markedly infrequent in experienced hands.

When vaporization is complete and hemostasis is verified, the bladder should be examined one more time to ensure there is no erroneous LASER damage. A catheter should then be placed, and irrigation of the bladder should verify clear (or nearly clear) irrigant.

Throughout the procedure, the surgeon should be aware of inefficient vaporization. Large bubbles should be visible coming from the tissue throughout vaporization as an indication of efficient energy use. When this is not seen, the LASER energy is being used inefficiently and most likely is causing coagulative necrosis or charring of the tissue. When the tissue is charred, the subsequent vaporization will be more challenging, leading to excessive energy usage. Unnecessary coagulative necrosis should be avoided as this will lead to more pronounced postoperative dysuria and possible passing of tissue per urethra.

Postoperative.

In almost all cases, the catheter can be removed the day of or the day after surgery. Bleeding should be minimal in the postoperative period, although patients will customarily pass some tissue with minimal bleeding 7 to 10 days from the surgery date. In cases of minor but continued bleeding, patients can be encouraged to increase fluid intake with careful outpatient follow-up. It is our custom to discharge patients home the day of surgery, with them removing the catheter the next day at home after the postoperative swelling of the prostate has significantly decreased.

Dysuria in the postoperative period can be exacerbated by technical inefficiency during the procedure, especially if tissue is being coagulated more than vaporized. The degree of dysuria is correlated with the volume of coagulated tissue (Choi et al., 2008). Patient characteristics that may lead to a risk for dysuria include a large median lobe, previous prostatitis, dense or fibrous prostate tissue, or previous treatments that change prostate tissue characteristics (TUNA, TUMT). **Generally, a sterile pyuria should be noted and can be treated with NSAIDs or a short course of a steroid taper if severe**. Although dysuria can be a common finding in these patients, the physician should always consider re-evaluation for an unexpected complication like a tissue flap or retained fiber fragment. Even in the best vaporizations, a layer of coagulated tissue will remain that could potentially lead to a subacute prostatitis and an increased risk for UTI. If a true infection is suspected because of either a prolonged dysuria or positive urinalysis/culture, culture-directed antibiotic therapy should be initiated, and culture should be considered after completed therapy.

Outcomes.

Rapid acceptance provided a considerable number of early studies looking at the outcomes of the lower-energy LASER fibers. As the manufacturer continues to update the LASER power over time, long-term results have become more difficult to incorporate into practice as a new power level is available frequently when research from the previous generation is being released. **Overall, the PVP technology has been viewed to have a forgiving learning curve with a**

favorable safety profile.

Single-Cohort Studies.

Hai and Malek (2003) published the first pilot study looking at the use of the 80-W KTP LASER. Ten patients were treated and then followed for 1 year. Significant improvements in AUA-SS, QoL score, Qmax, and PVR were noted initially with durability to 1 year. This was quickly followed by the multicenter trial study of 145 patients (Te et al., 2004). Once again, **improvements 12 months after the procedure were noted in AUA-SS (–82%), QoL score (–77%), Qmax (190%), and PVR (–78%).**

The change in urodynamic parameters even with the 80-W LASER was encouraging. In urodynamically obstructed patients who underwent PVP, a decrease in Schafer obstruction grade from 3.6 to 1.1 was noted at 12 months ($P < .0001$) with a decrease in PdetQmax from 75.0 to 36.6 cmH_2O (Hamann et al., 2008). The authors also found that the mean number of nighttime voids (3.5 to 1.2) and daytime voids (7.2 to 5.7) decreased with treatment.

Data became available on the 500 patients treated with the 80-W fiber in 2008 (Ruszat et al., 2008)**. With a mean follow-up of 30.6 months, the results of patients with 3 years of follow-up showed a mean AUA-SS of 8.0, QoL of 1.3, and a Qmax of 18.4 mL/sec.** In patients with 5 years of data (only 5.4% of the cohort), there was no appreciable difference in these numbers compared with the data at 3 years. The retreatment rate of the cohort was 6.8%, with a rate of urethral strictures of 3.6% and 4.4% for bladder neck contracture. Dysuria and bladder neck contractures were more common in smaller glands, but larger glands did not lead to a higher risk for retreatment. In another study evaluating the use of the 80-W LASER in large prostates, reintervention because of residual adenoma was 23% in the larger-gland (>80 g) group compared with only 10.4% ($P = .09$) in the group with glands less than 80 g (Pfitzenmaier et al., 2008).

As the improved hemostatic qualities of the LASER were recognized, challenging patients populations were tested. Patients requiring anticoagulation were able to be safely treated (Sandhu et al., 2005). Although many of the other endoscopic treatments were not rigorously tested on large glands, the improved visualization during vaporization allowed many early adapters to attempt treatment of large glands (>80 g). The International GreenLight Users (IGLU) group compiled some of the early data on 120-W LASER treatment of patients both with large glands and undergoing anticoagulation (Woo et al., 2008). For all the studied patients, there were improvements in Qmax, PVR, AUA-SS, and prostate volume compared with baseline. **The use of anticoagulants did not significantly increase complications. Large glands did not alter outcomes beyond the expected larger change in prostate volume.** A reduction of 52.5% was seen in larger glands compared with 42.3% in glands less than 80 g (*P* < .001).

Retrospectively reviewed 3-year results of the 120-W HPS reported durability and indicators of response (Cho et al., 2012). Preoperative AUA-SS was 21.7, which nadired to 11.5 at 6 months but was not statistically higher at 3 years (13.4). Maximum flow followed a similar pattern, improving to 15.7 mL/sec from 8.7 mL/sec at 6 months, with a value of 13.9 mL/sec at 3 years. Predictors of response were reported as AUA-SS greater than 19, with even higher scores being more likely to respond. Patients customarily underwent UDS, and the BOO index (BOOI) and bladder contractility index were predictors of a favorable outcome. Operative time and energy used during the procedure were interestingly not predictive.

Reoperation rates specifically for residual LUTS/BPH for the 180-W XPS system have proven to be better than previous generations although are **likely affected by the energy density (kJ/cc of prostate tissue) used during surgery.** In the longest study to date, with a mean follow-up of 57 months on 84 patients, an overall reoperation rate of 4.8% was noted, although **only 2.4% of the overall cohort had another surgery specifically for residual BPH.** The authors used a robust mean energy density of 5.3 kJ/cc. IPSS scores decreased from a preoperative average of 19.9 to 3.9 at 12 months increasing to 5.9 at the final visit for patients included (Calves et al., 2017).

In a multicenter study of 440 patients stratifying surgical outcome by four different energy densities (<3 kJ/cc, 3 to 5 kJ/cc, 5 to 7 kJ/cc and >7 kJ/cc), there were no statistical differences with regard to intraoperative or postoperative complications among groups. However, **all of the cases for retreatment of residual BPH occurred when less than 5 kJ/CC were used and principally occurred if less than 3 kJ/cc were used** (Valdivieso et al., 2016). Not surprisingly, a larger PSA decrease was noted with an increasing use of energy density with the greater than 7 kJ/cc group, noting a median decrease of 83%. Interestingly, the less than 3 kj/CC group had larger prostates, had a higher preoperative IPSS score and were more likely to come to surgery with a catheter in place.

Comparative Studies.

In the first RCT comparing 80-W PVP to TURP, Bouchier-Hayes et al. (2006) compared the results of trainees who had performed between 35 and 325 TURPs but had done at most 5 LASER prostatectomies. They exhibited comparable improvements in Qmax (149% for TURP, 167% for PVP) and AUA-SS (roughly 50% decreases in both groups). **This study exhibited the relative ease of performing the procedure and went on to conclude that PVP was 22% cheaper than TURP, primarily because of the shorter hospital stay**. Another RCT comparing the 80-W PVP and TURP focused on patients with glands larger than 70 g (Horasanli et al., 2008). Operating time favored TURP, and time in the hospital and time with a catheter favored PVP. Differences in the final AUA-SS, Qmax, and PVR favored TURP within the follow-up period. Blood transfusion was more common in the TURP group, and the PVP group had an increased risk for postoperative retention and need for reintervention (17.9% in the first year). The summary of these results demonstrated the excellent safety profile but decreased efficacy of the lower-energy PVP (especially in larger glands).

In an RCT of the 120-W HPS to TURP, Al-Ansari et al. (2010) found dramatic improvements in Qmax, AUA-SS, and PVR in both groups out to 36 months. **TURP did outperform in many metrics (Qmax, AUA-SS, PVR, mean PSA, mean prostate volume), although the differences were not statistically significant.** Although intraoperative complications were significantly fewer in PVP, a strikingly high 93% experienced dysuria or urge, and 11% required retreatment for residual adenoma (compared with only 1.8% of the TURP group, $P = .001$). Mean catheterization and mean hospital stay did favor PVP. Another RCT looking at the HPS versus TURP was completed the following year (Capitán et al., 2011). Once again, similar improvements were seen in Qmax, AUA-SS, and QoL, but these improvements appeared to nadir more rapidly in the PVP group. Interestingly, the authors stratified the AUA-SS questionnaire by symptom type and did not find an increase in storage symptoms for the PVP group. Intraoperative, early, and late complications did not differ between groups.

In their review of both 80-W and 120-W RCTs, Thangasamy et al. (2012) consistently found that catheterization and hospital stays were shorter in patients undergoing PVP by 1.91 and 2.13 days, respectively. Operative times were shorter in the TURP cohort by almost 20 minutes, with PVP having a risk ratio of 0.16 for blood transfusion compared with TURP. Other complications were not statistically different. In this review of 80-W and 120-W RCTs, six of the nine studies found no differences in functional outcomes. The one study that favored PVP was an 80-W study that never appeared to reach final publication with the two studies favoring TURP both specifically looked at patients with large prostates (>70 g) and had a LASER power of 80 W. In the analysis of 120-W PVP, Cornu et al. (2015) found a decrease in catheter time (mean 23 hours) and length of stay in hospital (mean 1.84 days).

Few studies have reliably compared the new XPS and previous HPS system. In a nonrandomized series of consecutive patients, Ben-Zvi et al. (2013) found that mean operating time and mean lasing time were decreased in the XPS group with comparable energy delivery. **The significantly different reductions in PSA (54% in HPS vs. 79% in XPS, *P* < .01) show that the XPS surely has a higher efficiency of tissue vaporization, although notable clinical parameters (AUA-SS, QoL, Qmax, PVR) were not different between groups.** Postoperative retention was higher in the HPS group (16% vs. 6%).

Since the last publication of this book, results from the landmark GOLIATH study have been released. This industry-sponsored study was a noninferiority trial comparing 180-W PVP to TURP at nine European centers with papers published with 6-, 12-, and 24-month data (Bachman et al., 2014, 2015; Thomas et al., 2016). The primary study outcome was IPSS at 6 months, with secondary outcomes including Qmax, freedom from complication, PVR, prostate volume, PSA, length of catheterization, length of hospitalization, convalescence time, and a variety of patient-reported measures. Individual cites had the option to choose monopolar or bipolar TURP at their discretion if patients were randomized to TURP.

A total of 281 patients underwent randomization. At the 6-month review, there were no statistical or clinically significant differences between groups with regard to IPSS, Qmax, or PVR (Bachman et al., 2014). A treatment-related adverse event was seen in 54% of PVP patients and 48% of TURP patients (*P* = .3). Self-reported incontinence was observed in 12% of PVP patients and 5% of TURP patients at 6 months with similar values between groups at 12 months (3%). No patient needed more than medical therapy to manage their incontinence. Storage urinary symptoms were similar between groups at the 6-month evaluation.

A large percentage of the cohort (89% of patients) were still in the study protocol at the 24- month visit (Thomas et al., 2016). **No differences were noted between the complication free rate and Qmax between groups. Final IPSS was 6.9 in the PVP group and 5.9 in the TURP group. Although this difference was statistically significant, it did not meet the predetermined**

IPSS difference of 3 for inferiority and is almost certainly not clinically significant. No differences were noted in PVR, prostate volume, PSA, or questionnaire data evaluating overactive bladder symptoms or erectile function.

Use of Photoselective Vaporization in Anticoagulated Patients.

A total of 116 men were included (36 on warfarin, 9 on clopidogrel, and 71 on aspirin), and all continued on their medications through the perioperative period while undergoing 80-W PVP (Ruszat et al., 2007). These groups were compared with 92 controls who were not on anticoagulants/antiplatelet medications. The control group was younger and had a lower ASA class. The average INR was 2.0 (range 1.3 to 2.9), with 14 of the 36 patients on warfarin having an INR of 2 or less. No patients required transfusion, but patients in the study group did have an increased hospital time (3.8 vs. 2.8 days) and were more likely to have CBI for 24 hours (17% vs. 5%). In particular, patients with an INR greater than 2 required CBI postoperatively. Other studies have shown the same risk for transfusion in a group of patients on mixed forms of anticoagulants or antiplatelet medications (Sandhu et al., 2005).

An uncontrolled study reporting on 43 patients continuing warfarin during surgery showed no patient requiring transfusion; two patients required prolonged catheterization subsequent to bleeding, but 70% of patients discharged to home within 24 hours of surgery (Woo and Hossack, 2011). A Cochrane review that compared LASER treatment methods with TURP found an overall reduced risk for transfusion with LASER prostatectomy (Hoffman et al., 2004).

Complications

Intraoperative and Perioperative.

Overall, the safety profile of PVP technology is excellent. **TUR syndrome** is not reported in any series as normal saline is used as irrigation. **Blood transfusion** is exceedingly rare, and patients on anticoagulation do not appear to be at a significantly increased risk. PVP had a lower risk (OR, 0.10) for perioperative blood transfusion when compared with M-TURP (Cornu et al., 2015).

Capsular perforation has been reported with PVP with ranges from 0.2% to 1% of cases (Rieken et al., 2010). Surgeons may find visualization of the capsule more difficult with the PVP, particularly early in the learning curve. Maintaining a proper sweeping motion and serially removing tissue in a circumferential fashion will avoid irregularities in vaporization depth and avoid perforation. In cases in which capsular perforation occurs, increased bleeding is generally noted, and conversion to TURP is more common (Bachmann et al., 2014, 2015).

Although rates are largely unreported, **ureteral orifice injury** can occur from errant LASER energy. The ureteral orifices should be identified before beginning the vaporization, and being careful not to extend the fiber into the bladder when vaporizing the bladder neck should minimize the possibility of this occurring.

Postoperative.

Postoperative dysuria and storage symptoms are not uncommon after PVP. In large series examining these outcomes, the adverse events were usually self-limiting and resolving spontaneously within 3 months. Anti-inflammatories, antibiotics, or even a short course of steroids may help the unhappy patient. The reported ranges of these symptoms range from 0% to 25.7% and are generally higher than data reported from TURP studies (Naspro et al., 2009), although this was not demonstrated in the GOLIATH study (Bachman EU 2014). As stated earlier, the inefficient use of LASER energy should be minimized to decrease unwanted outcomes. In a small series of patients, Matoka and Averch (2007) found that preoperative finasteride use and lower preoperative AUA-SS were predictors of postoperative irritative symptoms.

Infectious complications may be more common after PVP because of the necrotic tissue that occurs with coagulation. **Epididymitis** has been reported in 5% to 7% of patients, with **UTI** reported in 1% to 20% of patients (Chughtai and Te, 2011). Treatment of these conditions may be more challenging because of the presence of the necrotic tissue and its ability to harbor and feed bacteria. The treating physician should consider longer courses of antibiotics in these patients.

As the sheath used for PVP is generally smaller than those customarily used for TURP, the risk for **urethral stricture** should be lower. The surgeon should minimize movements of the sheath with a preference for LASER fiber movement to further lower this risk. Only 2.8% of patients had urethral stricture, and a relative risk of 0.65 was calculated compared with TURP (Thangasamy et al., 2012). A more recent meta-analysis did not verify this finding as comparable rates of stricture (and **bladder neck contracture**) were found between 120-W PVP and M-TURP (Cornu et al., 2015).

Reoperation rates specifically for residual adenoma vary significantly based on study and LASER power used. In their summary of PVP technology, Gravas et al. (2011) compared the reoperation rates of 80-W KTP with TURP at different time frames. The rates were 18% versus 0% after 6 months, 10% versus

3.4% after 12 months, and 6.7% versus 3.9% after 24 months for PVP and TURP, respectively. Other authors have found rates of 7.7% (Hai, 2009) and 6.8% (Ruszat et al., 2008) at 5 years, although both studies had high attrition rates. In an analysis of only 120-W studies, a slight increase in need for reoperation for residual BPH was found, but the authors commented on an overall small sample size (Cornu et al., 2015).

The 24-month 180-W GOLIATH data had three PVP patients (2% of PVP cohort) requiring reoperation for residual adenoma (Thomas et al., 2016), with only 2.4% in the 57-month series from Calves et al. (2017). **The increased energy density able to be delivered by the 180-W system may help mitigate this risk, with need for BPH-specific reoperations** (1.7% at 24 months) seen only in lower-energy densities shown in the series by Valdivieso et al. (2016).

Changes in **erectile function** in patients undergoing PVP are still being more clearly elucidated, but early results are encouraging. In 105 men undergoing PVP who completed SHIM scores preoperatively and 12 months after surgery, there was clearly no worsening of erectile function. In those men who were catheter free before surgery, statistically insignificant improvements were seen in erectile function (Kavoussi and Hermans, 2008). Mild but statistically significant improvements were noted in all IIEF-15 subdomains in a similarly structured trial of 45 men (Paick et al., 2007).

Conclusion.

Early LASER techniques focused on coagulation, with more contemporary techniques using LASER power to vaporize large portions of the prostate in an essentially bloodless field. **Although coagulation is still part of the LASER vernacular, a de-emphasis on broad coagulation has championed less postoperative irritative symptoms with a preference for LASER technology that chiefly leads to prostate vaporization.**

The early and lower-power PVP technology appears to have been less efficient against larger prostate glands with long operative times and cautionary retreatment rates. As the LASER energy has improved, both durability and operative times have improved. The excellent hemostasis and vaporization of the PVP technology have allowed for the treatment of many challenging patients, such as those on anticoagulation, who have not been attempted with many other endoscopic treatments of BPH.

Thulium

Concept and Introduction.

The thulium (Tm:YAG) LASER is a continuous wave of 2013-nm energy and has recently been introduced for the treatment of BPH. With a similar wavelength to the holmium LASER, this undergoes absorption in the irrigant but without the intermittent nature of holmium. The continuous energy emission has been suggested to lead to a cleaner incision, and with a slightly shorter wavelength than holmium, absorption by tissue is theoretically more pronounced and efficient (Chung and Te, 2009). However, such claims are putative until scientific proof is offered.

As the emitted wavelength reaches closer to the ideal in soft tissue, theoretically there will be a decrease in scattered thermal damage (Schomacker et al., 1991), which may lead to decreased scarring and stricture formation. However, in an animal model there was a wider thermal damage zone than predicted, and it was similar to that seen with holmium (Fried and Murray 2005).

Technique.

Like other LASER technologies, thulium may be used to either vaporize or incise tissue, although early clinical use has been to incise tissue to enucleate the transition zone of the prostate. This technology has introduced a new technique wherein the prostatic lobes are “peeled like a tangerine” off the prostatic capsule (Xia, 2009). The anatomy followed during prostate enucleation with thulium is similar to that done during HoLEP. The procedure is essentially analogous to HoLEP including morcellator use when the surgeon selects this option.

Some authors have utilized a resection-type technique wherein multiple incisions are made in the prostate parenchyma down to the capsule. Smaller sections of prostate are then liberated from the capsule leading to small prostate chips that can be irrigated through the resectoscope sheath. This eliminates the need for using the often troubling morcellator.

Catheter drainage is maintained at least overnight and can customarily be removed once hematuria has resolved (usually 1 to 3 days postoperatively). Patients can generally be discharged to home the same day as catheter removal.

Outcomes

Single-Cohort Series.

In an early retrospective review on the technology, 56 patients were reviewed (Szlauer et al., 2009). Maximum flow at day of discharge was improved from 8.1

mL/sec to 19.3 mL/sec, with a decrease in average residual urine to 57 mL from 151 mL. At a median follow-up of 9 months, PSA was reduced by 56% and the AUASS decreased from 19.8 to 8.6. The authors pointed out a slightly lower acquisition cost for thulium compared with holmium. They did estimate that 56% to 70% of the tissue was removed by their “vaporesection” approach compared with 30% to 85% for HoLEP.

Bach et al. reviewed patients who underwent enucleation and morcellation (“vapoenucleation”) with at least 12 months of follow-up (Bach et al., 2010). At 12 months, maximum urinary flow rate improved from 3.5 to 23.3 mL/sec (range of 6.6 to 47.9 mL/sec). AUASS decreased from 18.4 to 6.8, with an improvement in QoL score from 4.6 to 1.5. Patients who had a preoperative TRUS volume greater than 60 g were not more likely to have improvements in voiding parameters.

In a study looking exclusively at patients with prostate volumes greater than 75 g, with 70% having a volume greater than 100 g, the AUA-SS decreased from 21.1 to 3.9, with a 248% increase in maximum flow. Mean prostate volume assessed by TRUS decreased from 108 to 13.8 g. PSA also decreased substantially from 9.53 to 0.93 ng/dL, and IIEF score improved by 1 point with treatment (Iacono et al., 2012).

Taken as a whole, the improvements seen with these thulium-based removals of the transition zone are largely equivalent to those seen with HoLEP.

Comparative Series

Thulium Resection vs. TURP.

In a randomized trial of 100 patients undergoing standard M-TURP versus thulium resection, thulium treatment was superior with regard to catheterization time, hospital stay, and perioperative hemoglobin change, although operative time was similar between groups (Xia et al., 2008). Both groups demonstrated a similar improvement in IPSS and detrusor pressure at Qmax at 12 months. Late-term complications were also similar within groups, with retrograde ejaculation being the most common. Changes in symptom scores and urodynamics were comparable between groups.

In a report published by Yang et al. (2013), 158 patients were evenly randomized to receive either B-TURP or thulium enucleation. Operative time was 18 minutes longer in the thulium group, but significant decreases were noted in catheterization and hospital days with thulium resection. AUA-SS, QoL score, Qmax, and PVR had similar outcomes between groups, even out to 18 months.

Tang et al. (2014) performed a systematic literature review and meta-analysis of studies comparing TURP and thulium resection. Both randomized and nonrandomized trials were included along with both monopolar and bipolar TURP. They found a statistically significant longer operative time in the thulium group, although the clinical significance of the 9-minute weighted mean difference is likely inconsequential. Neither technique displayed consistent superiority with regard to AUA-SS, QoL score, PVR, or Qmax. The authors were also able to analyze complication rates and demonstrated decreased odds of receiving transfusion with thulium resection (OR 0.28, $P = .04$). Complications they deemed as “local” including need for re-catheterization, incontinence (stress or urge), UTI, and retrograde ejaculation did not have significant differences between treatment options. Thulium did seem to display lower odds of developing urethral stricture (OR 0.29, $P = .007$).

Thulium Enucleation vs. HoLEP.

Zhang et al. (2012) published a randomized comparison of thulium and holmium enucleation. A total of 133 consecutive patients were randomized to a similar enucleation technique with the different fibers at a single center. **Thulium required a longer operation time by approximately 10 minutes, with similar outcomes regarding postoperative AUA-SS, Qmax, and PVR**. PSA reductions were more modest than in most other enucleation studies (30% in the HoLEP group and 43% in the thulium group) but were not statistically different when compared. Complications were sparsely reported, but there was no appreciable difference in catheterization times.

Netsch et al. (2017) recently published the data of their randomized trial comparing thulium (48 patients) and holmium (46 patients) laser enucleation of the prostate. Preoperative prostate volume (median 80 g), Qmax (median 10.7 mL/sec), and IPSS (median 20) were similar between groups. Enucleation time was significantly longer in the HoLEP group (40 min) compared with the thulium group (27.03 min), although overall operative time was similar (60 min). The authors attributed this to the faster enucleation of the continuous wave mode of the thulium:YAG laser, which also yields a more shallow depth of coagulation (2 mm) compared with the holmium:YAG laser (4 mm). Patients in both groups achieved statistically significant improvements in IPSS, QoL, Qmax, and PVR, with no differences observed between groups. No difference in intraoperative complications were observed between groups, although the incidence of acute postoperative urinary retention was higher after HoLEP compared with thulium (15.2% vs. 2.1%).

Complications

Intraoperative and Perioperative.

The learning curve associated with resection of the prostate has not been adequately studied, but it is safe to assume that it will be similar to HoLEP. Most studies either did not report, or did not have any intraoperative complications. In a study using the morcellator for evacuation of prostate lobes after enucleation, no patients suffered from incomplete morcellation or ureteric orifice injuries, but 1.3% had bladder wall injuries resulting from the morcellator (Iacono et al., 2012), which is similar to the results reported by Netsch et al. (2017).

Postoperative.

Bach et al. (2010) analyzed early complications and defined rates of symptomatic UTI (6.8%), bleeding (5.6%), and immediate retreatment for residual BPH (2.2%). Blood transfusion was required in 2.2% of patients. Mild storage symptoms were observed frequently (27%), but most resolved within 1 month of surgery. They found with a cutoff prostate size of 60 cc, there was no difference in rates of complications based on prostate size.

In one of the first thulium enucleation studies published, a prohibitively high reoperation rate of 10.7% was seen in the relatively short follow-up period (Szlauer et al., 2009)**. The most common was need for reoperation for residual prostate hyperplasia and was attributed primarily to the learning curve associated with the procedure as all of these occurred within the first 20 cases.** The authors used a technique wherein the prostate is resected off the capsule in small pieces (“vaporesection,” not true enucleation) and commented that they felt the learning curve for this technique would be shorter than that for HoLEP.

In their series of large prostates (all >75g) undergoing thulium resection, 2.7% of patients required early recatheterization after surgery. Continued postoperative hematuria resulted in 2.7% of patients requiring blood transfusion. Transient urge incontinence was noted in 6.7% of patients, but all of these had resolved at 1-year follow-up. UTI was reported in 12.8% (Iacono et al., 2012).

Long-term complications appear to be comparable to other minimally invasive surgical techniques. Gross et al. (2017) reported that in their retrospective data of 500 consecutive thulium vapoenucleation cases, the rate of bladder neck contracture or urethral stricture was 3.1%, and the total retreatment rate was 8.4% at 5 years.

Conclusion.

Initial results from this new LASER technology are encouraging. It appears that there is potentially an improvement in tissue removal rate compared with other technologies because of the combined vaporization/incision that occurs with this technology. Theoretically it may have advantages compared with holmium enucleation with regard to tissue interaction, but certainly more populated and longer studies are required to evaluate this newcomer.

Key Points

- LASER treatments are the fastest-growing option in treatment of LUTS/BPH but should be used as part of a “culture of safety” in the operating room.
- HoLEP is a very effective treatment option with excellent results that are often comparable to those historically seen with OP. There is a significant learning curve associated with the procedure, and catastrophic complications (mostly caused by the morcellator) have been observed.
- PVP is a growing and very safe treatment option for BPH/LUTS. Results in patients on anticoagulation have been encouraging.
- Thulium is the newest addition to the LASER family and has some theoretical advantages, although scientific data are lacking.

Failed, Failing, and Future Directions

Prostate Stents

Concept

The concept of placing a stent into the prostate for relief of infravesical obstruction has a long track record. Stents can be classified into many categories including temporary or permanent, epithelializing, or nonepithelializing. Generally, the temporary varieties are used to combat the edema that accompanies many of the minimally invasive treatments options and are removed when the edema has resolved. **Although previously used on a wide variety of patients, permanent stents have largely been relegated to use in older men with medical comorbidities that severely restrict their treatment options because of the inability to tolerate any level of anesthesia.**

The mechanism of action of these prostatic stents is straightforward. The stent provides a rigid framework that, once in place in the prostatic fossa, pushes outward to open the prostatic lumen. In the epithelializing version, the stent is incorporated into the urethra as the urothelium grows into the stent, which should prevent encrustation or migration. Although commonly used for treatment of the enlarged prostate, other indications wherein stents have been used in the urethra include the treatment of detrusor-sphincter dyssynergia (Chancellor et al., 1999; Chartier-Kastler et al., 2000; Gajewski et al., 2000), postbrachytherapy obstruction (Konety et al., 2000), and complications of radical prostatectomy (Meulen et al., 1991).

The no longer produced UroLume (previously from American Medical Systems, Minnetonka, MN) was an epithelializing permanent stent composed of alloy wire in a woven shape that can expand to 42 Fr within the prostatic urethra. It came in varying lengths with a stent as short as 1.5 cm. As a result of issues with this stent (i.e., incomplete epithelialization leading to encrustation, stent migration), second-generation stents were developed including the Memokath (Pnn Medical, Kvistgaard, Denmark). These spiral stents expanded when flushed with hot water, with a portion of them securing at the prostatic apex.

Data

Initial clinical trials in the United States and Europe demonstrated efficacy in treatment of LUTS/BPH. In a study by Oesterling et al. (1994), patients were grouped into those with urinary retention and those without retention. In the nonretention group, 80 of the 95 patients were able to be evaluated at 12 months, and 52 had data available at 24 months. The Madsen symptom score decreased from a modest 14 to 5.9 and 5.4 at 12 and 24 months, respectively. The maximum urinary flow increased from 9.1 to 13.0 and 13.1 mL/sec respectively. In the retention group, a mean Madsen symptom score of 6.1 was noted at 12 months. This group had a Qmax of 11.7 mL/sec at 1-year post-treatment.

The European equivalent of this study examined 135 healthy men of whom roughly one-third had retention (Guazzoni et al., 1994). In the nonretention group, the Madsen score decreased from 14.1 to 6.4 at 12 months, with an increase in Qmax from 9.3 to 15.7 mL/sec. In the retention group, the mean symptom score was 4.5 after stent placement, and the Qmax was 13.1 mL/sec.

Masood et al. (2004) reported on 62 men with a follow-up of 12 years. A total of 47% of the stents were removed for a variety of reasons including malpositioning, migration, and patient satisfaction. Most (62%) of these removals occurred within the first 2 years after stent placement. The authors cautioned the use of careful case selection and surgeon experience.

In a review of results on the UroLume, of 176 men who could be identified as depending on catheterization before stent placement, 84% were able to void spontaneously after stent placement (Armitage et al., 2007).

Perry et al. (2002) reported on the use of a Memokath stent in 211 men who were unfit for surgery, with a reduction in AUA-SS of 59.6% at 3 months and almost no change in the next 7 years. The authors interestingly observed that these frail older men were more likely to die with their stent in situ (38%) than to require removal (23%).

A similar study on 144 men considered unsuitable for surgery over 17 years found that 79% of men who were in urinary retention could void spontaneously after stent placement. Stent failure was defined as removal, replacement, or reposition of the stent, with 38% of stents that were placed defined as a failure (Sethi et al., 2017).

Conclusion

Although originally a popular procedure for men who were unfit for surgery, the clinical application broadened but eventually was abandoned, except as a palliative procedure or in patients who are unable to tolerate any other procedure because of medical comorbidities. **The high failure and removal rates, with a**

sometimes challenging removal, were overall prohibitive, especially compared with many other suitable options.

Temporary Implantable Nitinol Device

Concept

The Temporary Implantable Nitinol Device (TIND) (Medi-Tate, Or Akiva, Israel) was developed to provide immediate relief from LUTS without the side effects of a permanent urethral implant. The device is composed of elongated struts and an anchoring leaflet, entirely composed of nitinol, which is a biocompatible superelastic shape-memory alloy widely used in medical devices. The total length of the device is 50 mm, and its outer diameter is 33 mm, allowing the device to cover the entire length of the prostatic urethra from bladder neck to a point just proximal to the external urinary sphincter. It is preloaded on a dedicated delivery system and is deployed in a folded configuration through a standard rigid cystoscope under light intravenous sedation. The device is then manipulated under direct visualization so that the anchoring leaflet slides into the 6 o'clock position distal to the bladder neck.

Once in place, the struts of the TIND expand and exert longitudinal pressure on the obstructing portion of the prostatic urethra and the bladder neck at the 12 o'clock, 5 o'clock, and 7 o'clock positions. The radial force exerted by the struts of the nitinol device is intended to cause ischemia, necrosis, and scarring of the prostatic urethra to “reshape” the prostatic urethra allowing urine to flow freely. On postoperative day 5, the TIND is retrieved in an outpatient setting using a standard 22-Fr cystoscope. As the device is retracted into the cystoscope sheath under visualization, it theoretically leaves the new channels in place.

Data

Initial proof-of-concept studies were performed using a retrievable PTFE-covered nitinol stent in a canine model by Crisostomo et al. (2007). Stent deployment under fluoroscopic guidance was successful in 7 of the 8 subjects and failed in 1 because of a narrow urethral lumen. Complete stent migration was seen in 2 animals at 1 month. Histologic analysis at 1 month revealed chronic inflammatory cell infiltrates, prostate glandular atrophy, periurethral fibrosis, and dilation of the prostatic urethra.

Porpiglia et al. (2015) published the first human results in their single-arm, prospective study of 32 patients with LUTS who underwent TIND implantation at the University of Turin between May 2010 and July 2013. Only patients with a prostate volume less than 60 g were included. All implants were placed under light sedation using a rigid cystoscope and were removed 5 days later in the outpatient setting. Patient underwent follow-up with IPSS, QoL, and uroflowmetry assessments out to 12 months.

Mean baseline prostate volume was 29.5 g, median IPSS 19, and QoL index 3. At 12 months mean Qmax increased from 7.6 to 11.9 mL/sec ($P < .01$), median IPSS improved from 19 to 9 ($P = .18$), and QoL index improved from 3 to 1 ($P = .45$) compared with baseline. Four patients (12.5%) presented with complications in the early postoperative period (<30 days); no late complications were reported. Complications included infection (6.2%), urinary retention (3.1%), and urinary incontinence 1 day after surgery (3.1%). One of the patients who developed an infection presented with a 2-cm prostatic abscess and was treated with medical therapy. In the patient who presented with urinary incontinence, cystoscopy revealed the distal portion of the device distal to the external sphincter, suggesting displacement of the device. The patient's urinary incontinence resolved on TIND removal. No patients underwent adjunctive surgical treatments during the follow-up period.

Verdict

Although the concept of a TIND is interesting, and preliminary studies have demonstrated its feasibility in a small cohort of patients, long-term safety and efficacy data are needed before drawing any concrete conclusions about this technology. Whether TIND permanently restructures the anatomy of the prostatic urethra remains to be proven.

Aquablation (Aquabeam)

Concept

This TRUS-guided technology utilizes a nonthermal high-velocity saline water jet stream to ablate prostate tissue. A real-time TRUS probe defines the treatment area, and a robotically guided transurethral system then quickly hydrodissects the target area. Hydrodissection times range over a few minutes and are only minimally affected by prostate size. As the treatment carefully carves out the transitional zone without possible thermal or anatomic injury to the bladder neck, external sphincter, or periprostatic nerves, the effect on continence, erections, and antegrade ejaculation should be minimized.

The AquaBeam system is manufactured by PROCEPT BioRobotics (Redwood Shores, CA) and includes a console/pump, a robotically controlled handpiece, and a TRUS probe (Fig. 146.19). The 24-Fr handpiece with integrated cystoscopy is inserted transurethrally into position and then locked into place via a bedrail-mounted articulating arm. After the biplanar TRUS probe is inserted, the surgeon plans the treatment zone. **The angle of resection is first selected followed by visualization of the prostate in the sagittal view to conform the treatment zone to the shape of the adenoma. The treatment zone is adjusted to exclude the bladder neck and external sphincter and focus on the adenoma.** Foot pedal activation by the surgeon initiates the treatment by guiding the high-velocity saline waterjet proximal to distal in a sweeping fashion through the prostate, with changes in the waterjet velocity regulating the depth of ablation of targeted prostate parenchyma. The treatment can be monitored by the ultrasound images and cystoscopic view. Hemostasis after the procedure can be achieved either with resectoscope or with a Foley catheter on traction.

Data

The first publication on aquablation was a prospective single-center nonrandomized study in men with moderate to severe LUTS/BPH (Gilling et al., 2016). An international, blinded, multicenter randomized controlled trial comparing aquablation to TURP quickly followed (Gilling et al., 2017). A total of 181 patients completed the 6-month follow-up. Improvements in IPSS for aquablation (22.9 to 5.9) and TURP (22.2 to 6.8) were both significant without a statistical difference between treatment modalities. **Change in IPSS was more pronounced, with aquablation for the 50- to 80-g prostate size subgroup ($P = .0099$).**

Operative times were similar between treatment options, with a much lower resection time for aquablation (4 vs. 27 minutes, $P < .0001$). Outcomes relating to ejaculation were better for patients undergoing aquablation (likely related to the sparing of the bladder neck with treatment), with other individual safety measures statistically similar between groups.

Verdict

With this new application of robotics, the transition zone can be precisely defined for treatment, which should ideally minimize undertreatment of the prostate adenoma. The procedure does require general anesthesia, making it difficult to characterize as a MIST but may demonstrate improvements over conventional BPH treatments like TURP.

Prostate Embolization

Concept

Despite the first reported case of prostatic arterial embolization (PAE) by DeMeritt et al. (2000), PAE did not gain more widespread use until recently. Access is generally gained at one of the femoral arteries, and pelvic angiography is performed to evaluate the iliac tree and prostatic arteries. **Once the catheter has been advanced into the prostatic arteries, an embolizing agent (e.g., alcohol, microspheres) is then infused through the catheter until stasis is seen in the prostatic vessels.** Access can be gained through one or both femoral vessels to perform unilateral or bilateral PAE, although it appears that bilateral procedures incur better results (Bilhim et al., 2013).

As seen commonly with embolization of blood-rich organs (e.g., kidney), a postembolization syndrome of pain and fever is customary. The incidence of post-PAE syndrome reported in the literature varies from 0% to 22%, the symptoms of which some authors argue may be mitigated by expectant medical management (Antunes et al., 2013, Gao et al., 2014, Grosso et al., 2015, Rampoldi et al., 2017). As tissue is not directly removed or ablated in PAE, theoretically local symptoms should be minimized; however, gaining the access to the femoral vessels may lead to local problems at that area including pseudoaneurysm or bleeding (Stone and Campbell, 2012). Additionally, intravascular contrast agents are used, making a contrast allergy a contraindication. The angiography needed during this procedure also exposes the patient to a significant amount of radiation exposure.

Possible technical problems include the inability to access the prostatic arteries because of tortuosity, vessel atherosclerosis, or aberrant pelvic arterial anatomy. In the study by Bilhim et al. (2012), the prostatic artery was found to arise from five different arterial trunks, with the most common site being the internal pudendal artery (34%). In 43% of the cases, there were two prostatic arteries on one side, with anastomoses to adjacent arteries also commonly found.

Data

Single-Cohort Studies.

Although the body of evidence regarding PAE is growing, the literature is primarily based on small cohort series concentrated in a handful of centers. It is important to note that there have only been two randomized trials published to date, both comparing PAE to TURP. Pisco et al. (2011) were first to report on a small series of patients who underwent PAE prospectively. They noted statistically significant improvements in AUA-SS (6.5 points, *P* = .005) at a mean follow-up of 7.9 months. Peak urinary flow only increased by 3.85 mL/sec (*P* = .015), and PSA and prostate volume decreased by 26% and 27%, respectively. The procedure was unable to be completed in 6.7% of patients, and 28.6% of patients met criteria for clinical failure. There was one major complication, an ischemic area of the bladder wall that required surgical intervention. Mean procedure time was 85 minutes (range 25 to 135 minutes), with patients undergoing a **mean fluoroscopy exposure time of 35 minutes** (range 15 to 45 minutes) (Pisco et al., 2011). Later studies have reported a mean fluoroscopy time ranging from 18 to 85.9 minutes, which in part, may be caused by the learning curve associated with the procedure (Kuang et al., 2017).

Antunes et al. (2013) included urodynamic data in their cohort of 11 patients who presented with urinary retention, with a prostate volume between 30 and 90 g. In this study, 10 of the 11 patients were catheter-free at a minimum follow-up of 12 months (mean follow up 22.3 months), and mean AUA-SS score at 12 months was 2.8 (range 1 to 7). UDS performed before and after treatment showed a decrease in detrusor pressure at Qmax from a mean of 85.7 to 51.5 cm H_2O. All patients had a BOOI greater than 40 before PAE. Post-PAE, only 30% of patients were clearly unobstructed (BOOI <20), 40% in the equivocal range (BOOI 20 to 40), and 30% demonstrated persistent obstruction (BOOI >40). Almost all patients reported mild, transitory pelvic pain, with three patients having minor rectal bleeding. One patient had an a focal area of hypoperfusion of the bladder wall on MRI at 1 month, which normalized on MRI at 90 days and 2 years.

Bilhim et al. (2013) investigated the effect of unilateral versus bilateral PAE in a single-center cohort study of 122 consecutive patients. A comparison of 103 patients who underwent bilateral PAE and 19 who underwent unilateral PAE revealed no statistically significant differences in change in prostate volume, PSA, IPSS, QoL, Qmax, PVR, or IIEF. A significant proportion of patients in both groups required medical therapy for persistent LUTS after PAE, 52% and 77.8% of patients in the bilateral and unilateral PAE groups, respectively. In addition, 20% of patients who underwent bilateral PAE went on to require prostatic surgery, compared with 11.1% of patients in the unilateral PAE group.

Pisco et al. (2013) published the largest series to date in their prospective nonrandomized single-cohort study of 255 patients with moderate to severe LUTS. PAE was technically successful (defined as bilateral arterial occlusion) in 250 patients (97.9%) and deemed clinically successful (defined as >25% reduction in IPSS and improvement in QoL by 1 point or QoL ≤3) in 72% at 18, 24, 30, and 36 months based on Kaplan-Meier curves. Clinical failure had no direct correlation with the reduction in prostate volume, although it appeared that failures were more common if only unilateral embolization occurred. At 6 months, patients saw a statistically significant improvement in IPSS, QoL, Qmax, and PVR. Prostate volume initially decreased from 83.5 g to 66.6 g at 6 months, but increased to 90.9 g at 24 months. Similarly, PSA initially decreased from 5.68 to 4.3 at 6 months, only to increase to 6.1 at 24 months. Both prostate volume and PSA at 24 months are based on available follow-up data for less than 15 patients, making these results difficult to interpret.

At 3 months, the mean AUA-SS was reduced by 54%, with a reduction in QoL score of 49%. Over the same period, maximum flow improved by 35%, prostate volume decreased by 18%, and IIEF score improved by 10.6%. In those patients with data at 1 year after the procedure, the absolute scores were not appreciably different from those at 3 months. It is important to note that despite the improvement in AUA-SS, on average, patients still had moderate LUTS at 6 months (mean AUA-SS was 11.5). Furthermore, the authors noted that there was no relationship between reduction in prostatic volume and clinical outcome, highlighting the disconnect of taking a prostatocentric approach.

Others have argued the utility of PAE it the treatment of larger prostate glands, which would traditionally be considered candidates for simple prostatectomy. In a single-center prospective study of 88 patients with a prostate volume greater than 80 g, with a mean prostate volume of 129.3 g, prostate size decreased to 71.2 g at 1 year. Patients also saw an improvement in IPSS (23.98 to 10.4) and Qmax (7.28 to 16.89 mL/sec). Wang et al. (2015) also looked at larger glands between 90 and 252 g (mean prostate volume 135 g), noting a similar improvement in IPSS from 18.3 to 2.7 at 3 months. Qmax also improved from

7.1 to 15.2 mL/sec at 3 months. Unfortunately, longer follow-up data were not available, making it difficult to extrapolate these results. Other authors who have also looked at prostate glands greater than 80 g with at least 18 months of follow-up have touted a clinical improvement rate ranging from 77.8% to 91.7% (Li et al., 2015; Pisco et al., 2016; Wang et al., 2015).

Comparative Studies.

In the first prospective randomized trial of 114 patients, Gao et al. (2014) compared PAE to bipolar TURP in men with a prostate volume between 20 and 100 g. The authors described clinical failure as persistent severe LUTS (decrease in IPSS of ≤25%, IPSS ≥18, decrease of QoL score by ≤1, and QoL score ≥4) and/or Qmax increase less than 2.5 mL and Qmax slower than 7 mL/sec. Despite using these generous criteria, they classified 9.4% of patients who underwent PAE as a clinical failure, compared with only 3.9% in the TURP group. Furthermore, patients in the TURP group showed greater degrees of improvement in IPSS, QoL, Qmax, and PVR at 1 and 3 months, a difference that was no longer evident at 12 and 24 months. The TURP group also saw greater reductions in PSA and prostate volume at all time points measured when compared with the PAE group. Patient in the PAE group were more likely to experience an adverse event or complication, primarily related to acute urinary retention, post-PAE syndrome, or treatment failure. The overall complication rate was 52.6% in the PAE group versus 29.8% in the TURP group. Although the authors noted that both urologists who performed TURP had several years of experience, qualifying this with a statement that before this study, both had “performed at least six bipolar TURP procedures,” this calls into question whether they were sufficiently experienced in TURP.

Carnevale et al. (2016) published the only other prospective randomized trial comparing 30 patients who underwent monopolar TURP versus PAE with a minimum of 1 year follow-up. Notably, mean procedure time was significantly longer in the PAE group compared with the TURP group, and times were 144.8 minutes and 61.7 minutes, respectively. This large discrepancy occurred despite the fact that prostate volume was similar between groups, TURP 56.6 g versus PAE 63.0 g. Although both groups experienced a statistically significant improvement in IPSS, at 12 months IPSS in the TURP group was 6.1 compared with 12.8 in the PAE group. Similarly, Qmax improved from 9.7 to 27.1 mL/sec, and the PAE group saw a modest improvement from 7.0 to 10.1 mL/sec, which is arguably clinically insignificant. In addition to the adverse events that has previously been described by others, they also reported an incident of asymptomatic transient pubic bone ischemia seen on MRI at 3 months.

Patients must be warned of the potential side effects/adverse events associated with PAE before its use, including the increased risk for need for reoperation, acute urinary retention requiring recatheterization, transfusion, urinary incontinence, rectal bleeding, hematospermia, pubic bone ischemia, hematuria, clot retention, alterations in ejaculate volume, postembolization syndrome, and severe pelvic pain. As intravenous contrast is used for the angiography portions, a contrast allergy is a contraindication for this procedure. Minimal local prostatic symptoms are generally seen; however, a generalized postembolization syndrome may ensue that includes fever or perineal pain. The more customary postprocedural voiding symptoms, however, are traded for possible complications of vascular access, including pseudoaneurysm and retroperitoneal bleeding.

Verdict

A technically challenging, and highly variable, pelvic anatomy may limit the widespread acceptance of this technology, with only expert interventionists performing the procedure. Completed studies have largely been nonrigorously performed, and application of the generated data makes it difficult to predict the role of prostate embolization in the treatment of LUTS/BPH. The many problems with these embolization reports include (1) reliance on imaging-based reduction in prostate volume, (2) naïve prostato-centric concepts of BPH, (3) lack of control patients, (4) unconventional definition of clinical improvement, (5) uniform failure to account for a placebo effect, thus leading one to assume that the improvement in LUTS or other outcomes were PAE related (intervention effect remains unknown), and (6) ignoring LUTS as the motivating complaint and the ultimate arbitrator of success.

Prostatic Injections

Concept

References to intraprostatic injection for management of prostate disease date back more than 100 years (Plante et al., 2004). The ease of application and overall low start-up costs make this an attractive option. **An injectable is**

commonly administered via a transperineal or transurethral approach into the prostatic parenchyma, with the injected substance theoretically causing localized changes to reduce prostate volume.

Although a wide variety of solutions have been tried in animal models, reported agents used in human studies include acid mixtures (Talwar and Pande, 1966), pepsin/iodine concoctions (Payr, 1936), ethanol, botulinum toxin A (BONT-A), and new agents with novel mechanisms of action.

Data

PRX302.

PRX302 is a novel injectable protein that is derived from the *Aeromonas hydrophilia* and manufactured by Sophiris Bio Inc. (La Jolla, California). **This pro-toxin that has been genetically modified to be activated by PSA (instead of its native furin), making it active only in the prostate. After being injected into the prostate parenchyma, the protein is cleaved by PSA, which activates the protein to oligomerize and form a transmembrane pore leading to cell death.**

The most recent publication on the medication is from 2013 and enrolled 92 men in a randomized double-blind phase IIb trial. A considerable placebo effect was noted as men were followed out to 1 year. Although improvements were noted above placebo at earlier time points, there was no statistical difference in IPSS at 1 year despite utilizing a P value of less than 0.1 for determining statistical differences between the treatment and control groups. No changes in sexual function were noted, and adverse events like pain with injection and voiding symptoms were mild. Interestingly, antibodies to PRX302 were noted in 73% of patients (Elhilali et al., 2013).

Further clinical trials are necessary before this medication could be considered a standard of care. Although imaginative in its approach, the lack of recent publication may be telling, although apparently ongoing trials are recruiting including a trial utilizing PRX302 as a focal treatment for prostate cancer.

Anhydrous Ethanol.

Anhydrous ethanol treatments of the prostate for LUTS/BPH have been primarily studied in non-US markets. Investigative trials are underway in the United States to allow ethanol to formally gain FDA approval for use in the prostate (Plante et al., 2007). **Although the mechanism of action with human**

prostate cells is not entirely delineated, it is likely that there are pro-apoptotic mechanisms that are induced (Plante et al., 2013). Other possible mechanisms include hemorrhagic coagulation necrosis caused by vessel thrombosis and occlusion (Goya et al., 1999).

In a study of 35 patients with a mean follow-up of 50 months (range 47 to 56 months), initial significant changes were noted in AUA-SS (–75%), Qmax (+247%), and prostate volume (–30%) at 3 months (Sakr et al., 2009). At 4-year follow-up, 25 of the initial 35 patients had data for reporting with improvements compared with preinjection of 55% in AUA-SS, 187% in Qmax, and 5.2% in prostate volume. Nine patients (26% of the initial cohort) required some form of retreatment (TURP, reinjection, or medical therapy) during the study period. In a study with a long follow-up but high attrition rate, 23% of patients required alternative treatment (El-Husseiny et al., 2011).

In 36 patients followed to 1 year after treatment, AUA-SS (46% reduction) and QoL scores (48% reduction) were significantly decreased at the last visit. Maximum flow improved throughout the study period, with improvements significant at 3 months (78%), 6 months (137%), and 12 months (154%). Reports on potential nonresponders and patients needing retreatment were not included, and it was unclear if these were consecutive patients (Magno et al., 2008).

In a phase I/II trial evaluating varying doses of ethanol injection, the most common reported adverse events were hematuria (42%), irritative voiding symptoms (39%), pain/discomfort (28%), and transient urinary retention (22%) when using absolute reporting (Plante et al., 2007). However, when stratified to AUA guidelines, these percentages were 0%, 2.7%, 5.4%, and 16.2%, respectively. Patients were randomized to a low, medium, or high dose adjusted for prostate size and had a roughly 50% decrease in AUA-SS and QoL scores across doses. Injection was done transurethrally, with the average procedure lasting 25 minutes. Moderate or severe pain during the procedure was reported by 6.7% and 12.2% of patients, respectively.

Botulinum Toxin.

BONT-A is produced by *Clostridium botulinum* with an already established use in urology for the care of patients with neurogenic voiding dysfunction. Although the exact mechanism to improve voiding when injected into the prostate is not completely understood, this exotoxin may have influence over both the static and dynamic components of BPH (Chuang et al., 2006a). In a placebo-controlled animal study, male rats 1 week after BONT-A injection were noted to have an increase in apoptotic cells with decreases in proliferative cells and the α_{1A} receptor. No significant change was noted in the presence of the androgen receptor. In rats sacrificed 2 weeks after injection, these effects were less notable (Chuang et al., 2006b). This was validated an earlier study wherein BONT-A injection lead to a generalized apoptotic atrophy of the rat prostate thought to be caused by denervation (Doggweiler et al., 1998). In an interestingly designed study, Silva et al. (2009) concluded that BONT-A induced prostate atrophy in the rat that may be the result of sympathetic nerve impairment, with the data indirectly suggesting that sympathetic neural drive played a role in prostate size regulation.

Lin et al. (2007) studied two doses of BONT-A (100 U and 200 U) on prostatic contractile function and structural changes and established a dose response. The higher dose produced a more pronounced atrophic change in the smooth muscles cells of the dog prostate. Under electrostimulation, prostate urethral pressure response was statistically lower in only the 200-U group.

A placebo-controlled trial in humans found a 65% reduction in AUA-SS at 2 months after injection. PSA was reduced by 51%, and prostate volume was reduced by 68% compared with baseline, corroborating the findings of induced cell atrophy seen in animal studies (Maria et al., 2003). Of the 15 patients receiving BONT-A injection, 13 noted improvements in voiding. No patients in the placebo group experienced benefits from saline injection. Four control group patients later received BONT-A, with 17 patients having longer follow-up data. Reductions in AUA-SS, serum PSA, Qmax, and prostate volume appeared durable at 1 year.

In a cohort of 60 patients with a prostate volume of more than 60 g with unsatisfactory response to combination medical therapy, 30 were randomized to BONT-A injection (Kuo and Liu, 2009). Although injection did reduce prostate volume and improve AUA-SS and QoL scores, the long-term therapeutic benefits were minimal compared with the control group. At 6 and 12 months after injection, only the QoL score in the study group was statistically different from the group continuing combination therapy. At the end of the study, three patients in the treatment group and two patients in the control group progressed to TURP for relief of LUTS. Surprisingly, despite not receiving any placebo drug or sham procedure, the control group had statistically significant improvements in AUA-SS, QoL score, and prostate volume at 6 and 12 months.

A phase II dose-ranging placebo-controlled RCT was published in 2013

(Marberger et al., 2013). Significant improvements from baseline values were found in AUA-SS, Qmax, and prostate volume at 12 weeks in all groups (including normal saline placebo). No significant differences were found between the doses of BONT-A and placebo. Adverse events were comparable across study groups.

A multicenter, double blind, sham-controlled study verified these results and included 315 patients (McVary et al., 2014b). Although decreases in AUA-SS were seen in both the BONT-A (–6.3) and placebo (–5.6) groups, there was no difference between BONT-A and placebo. **Authors concluded that although the treatments were well tolerated, no increased efficacy was seen with BONT-A over saline injection.**

Verdict

The simplicity of delivery for prostate injections makes it theoretically an attractive option for a MIST for LUTS/BPH. A significant placebo effect is frequently noted, with medication effects often not outpacing the improvements over vehicle or placebo.

Conclusion

Although OP and M-TURP had high complication rates, they did provide an excellent treatment to the age-old problem of LUTS/BPH. Many new suitors have been introduced to the market to achieve maximum results with a more acceptable safety profile, but each new technology led us to previously unconsidered complications and new paradigms to consider. The trainee and even veteran urologist should be conscious to carefully examine the results of each new treatment as new studies frequently attempt to mislead or overstate their results by not including a rigorous design or adequately controlling for a placebo/sham effect.

The gold standard operation for any patient is the one that meets his or her needs and expectations while still being safe. This decision for which technique is ideal should include a careful consideration of patient factors, but the surgeon's familiarity and ability to safely perform the selected procedure should also be a factor.

Simple Prostatectomy

Open and Robotic-Assisted Laparoscopic Approaches

Misop Han MD, MS, Alan W. Partin MD, PhD

The treatment options for bladder outlet obstruction resulting from benign prostatic hyperplasia have greatly expanded over the past three decades with the development of improved medical and minimally invasive surgical therapies. Newer minimally invasive procedures include visual laser ablation of the prostate (Cowles et al., 1995), transurethral electrovaporization of the prostate (Kaplan et al., 1996), transurethral needle ablation (Campo et al., 1997; Schulman et al. 1993), transurethral microwave thermotherapy (Ogden et al., 1993), interstitial laser coagulation (Muschter and Hofstetter, 1995), bipolar transurethral resection of the prostate (bipolar TURP) (Botto et al., 2001; Eaton and Francis, 2002), and transurethral incision of the prostate (Cornford et al., 1997). However, these approaches are usually reserved for men with moderate symptoms and a small- to medium-sized (up to 75 g) prostate gland (Reich et al., 2006). For larger prostate glands, open simple prostatectomy has been frequently performed, although it is usually associated with a longer hospital stay and a larger blood loss (McVary et al., 2011). Lately, holmium laser enucleation of the prostate (HoLEP) with the holmium:yttrium-aluminum-garnet (Ho:YAG) laser has been performed as a minimally invasive alternative to open surgery (Comat et al., 2017; Gilling et al., 1998). However, the learning curve with HoLEP is considered steep (Robert et al., 2016). Most recently, as urologists have gained experience in minimally invasive therapy, a simple prostatectomy has been performed more frequently using a robotic-assisted laparoscopic approach (Holden and Parsons, 2016; Sotelo et al., 2008). **This chapter describes simple prostatectomy technique using an open and robotic-assisted laparoscopic**

approach.

For patients with acute urinary retention, persistent or recurrent urinary tract infections (UTIs), severe hemorrhage from the prostate, bladder calculi, severe symptoms unresponsive to medical therapy, and/or renal insufficiency as a result of chronic bladder outlet obstruction, TURP or simple prostatectomy is indicated. **When compared with TURP, simple prostatectomy offers the advantages of a lower retreatment rate and more complete removal of the prostatic adenoma under direct vision and avoids the risk for dilutional hyponatremia (the TUR syndrome) that occurs in approximately 2% of patients undergoing traditional monopolar TURP** (Roos et al., 1989). Several contemporary series have demonstrated objective improvement in urinary symptoms after simple prostatectomy (Lucca et al., 2015; Varkarakis et al., 2004). **The disadvantages of open simple prostatectomy, compared with those of TURP, include the potential for perioperative hemorrhage, the need for a lower midline incision, and a resultant longer hospitalization and convalescence period. However, robotic-assisted laparoscopic simple prostatectomy results in a significantly decreased risk for perioperative hemorrhage and transfusion** (Holden and Parsons, 2016).

Open simple prostatectomy can be performed by either the retropubic or the suprapubic approach. **In retropubic prostatectomy, the enucleation of the hyperplastic prostatic adenoma is achieved through a direct incision of the anterior prostatic pseudocapsule.** This approach to open simple prostatectomy was popularized by Terrence Millin (Millin, 1945). **The advantages of this procedure over the suprapubic approach are (1) excellent anatomic exposure of the prostate, (2) direct visualization of the prostatic adenoma during enucleation to ensure complete removal, (3) precise transection of the urethra distally to preserve urinary continence, (4) clear and immediate visualization of the prostatic fossa after enucleation to control bleeding, and (5) minimal to no surgical trauma to the urinary bladder. The disadvantage of the retropubic approach, as compared with the suprapubic prostatectomy, is that direct access to the bladder is not achieved.** This may be important when one considers excising a concomitant bladder diverticulum or removing bladder calculi. The suprapubic approach also may be the preferred method when the obstructive prostatic enlargement includes a large intravesical median lobe.

Suprapubic prostatectomy, or transvesical prostatectomy, consists of the enucleation of the hyperplastic prostatic adenoma through an

extraperitoneal incision of the lower anterior bladder wall. This approach to open prostatectomy was first performed by Eugene Fuller in New York in 1894; it was later popularized by Peter Freyer in London, United Kingdom, who described the procedure in 1900 and later reported the results of his first 1000 patients in 1912 (Freyer, 1900, 1912). The major advantage of this suprapubic procedure over the retropubic approach is that it allows direct visualization of the bladder neck and bladder mucosa. **As a result, this operation is ideally suited for patients with (1) a large median lobe protruding into the bladder, (2) a clinically significant bladder diverticulum, or (3) large bladder calculi. The disadvantage, compared with the retropubic approach, is that direct visualization of the apical prostatic adenoma is reduced. Furthermore, hemostasis may be more difficult because of inadequate visualization of the entire prostatic fossa after enucleation.**

Since the performance of the initial laparoscopic radical prostatectomy in 1997 (Schuessler et al., 1997) and the introduction of the da Vinci Surgical System (Intuitive Surgical, Sunnyvale, CA) in 2000, the minimally invasive approach, especially the robotic approach, for radical prostatectomy has gained wide popularity. As urologic surgeons gain more experience with robotic instruments, the robotic-assisted laparoscopic simple prostatectomy has gained acceptance (Holden and Parsons 2016; Sotelo et al., 2008). **The major advantages of the robotic-assisted laparoscopic simple prostatectomy approach over the open approaches are excellent hemostasis, negligible need for transfusion, shorter hospital stay, and better visualization because of pneumoperitoneum and magnification.** This approach also can manage a large median lobe, bladder diverticulum, or large bladder stones. **The disadvantages of robotic-assisted laparoscopic simple prostatectomy, compared with the open approaches, include the need for a general anesthesia and a longer operative time, especially in the initial experience** (Matei et al., 2012)**. Therefore, robotic-assisted laparoscopic simple prostatectomy should be considered by urologic surgeons who have extensive experience in robotic surgery, especially in robotic-assisted laparoscopic radical prostatectomy.**

Indications for Simple Prostatectomy

The indications for prostatectomy, by either an open or robotic-assisted laparoscopic approach or transurethral resection, include (1) acute urinary retention; (2) recurrent or persistent UTIs; (3) significant symptoms from bladder outlet obstruction not responsive to medical therapy; (4) recurrent gross hematuria of prostatic origin; (5) pathophysiologic changes of the kidneys, ureters, or bladder secondary to prostatic obstruction; and (6) bladder calculi secondary to obstruction.

Simple prostatectomy should be considered when the obstructive tissue is estimated to weigh more than 75 g. If sizable bladder diverticula justify removal, suprapubic or robotic prostatectomy and diverticulectomy should be performed concurrently. If the prostatectomy is performed without the diverticulectomy, incomplete emptying of the bladder diverticulum and subsequent, persistent infection may occur. Large bladder calculi that are not amenable to easy transurethral fragmentation also may be removed during the procedure. Simple prostatectomy should be considered when a patient presents with ankylosis of the hip or other orthopedic conditions that prevent proper positioning for TURP. Also, it may be wise to perform a simple prostatectomy in men with recurrent or complex urethral conditions, such as urethral stricture or previous hypospadias repair, to avoid the urethral trauma associated with TURP. Finally, the association of an inguinal hernia with an enlarged prostate suggests a simple procedure, because the hernia may be repaired by the same lower abdominal incision (Brunocilla et al., 2005; Schlegel and Walsh, 1987) **or laparoscopically/robotically** (Do et al., 2011; Nakamura et al., 2011)**.**

Contraindications to simple prostatectomy include a small fibrous gland, the presence of significant prostate cancer, and previous pelvic surgery that may obliterate access to the prostate gland.

Preoperative Evaluation

In deciding whether to perform a simple prostatectomy for symptomatic obstruction resulting from benign prostatic hyperplasia, it may be necessary to consider the upper and lower urinary tracts. Usually the patient will have already completed the International Prostate Symptom Score (IPSS) questionnaire and had a peak urinary flow rate determination. The postvoid residual urine volume also may have been verified with abdominal ultrasonography. **A cystoscopic examination is not indicated in the routine evaluation of a patient with obstructive voiding symptoms**. **However, cystoscopy should be performed in men with hematuria, suspected urethral stricture, and bladder calculus or diverticulum.** It also can be helpful in confirming the presence of a large median lobe or in assessing the length of the prostatic urethra.

Before performing a simple prostatectomy, the presence of significant prostate cancer should be determined. All men should undergo a digital rectal examination and have a serum prostate-specific antigen determination. If the digital rectal examination detects induration or nodularity, or the serum prostate-specific antigen level is elevated, a biopsy of the prostate gland should be performed. **Men participating in an active surveillance program for a very low-risk prostate cancer may consider a simple prostatectomy for symptomatic obstruction if they clearly understand the potential risks and benefits of the surgery. The upper urinary tracts should be evaluated preoperatively in men with known renal disease, abnormal renal function, recurrent UTI, or hematuria.**

Before surgery, the patient should undergo a complete medical evaluation consisting of a detailed history, thorough physical examination, and appropriate laboratory assessment.

Men in urinary retention should have an evaluation of renal function. If the serum creatinine value is elevated, surgery should be delayed until this parameter stabilizes. Urinalysis is performed to rule out a UTI, and a urine specimen should be sent for culture and sensitivity if an infection is suspected. If an infection is present, appropriate antimicrobial therapy must be instituted before surgery to prevent urinary sepsis (Serretta et al., 2002).

Historically, 3% to 10% of men undergoing an open simple prostatectomy will require 1 or more units of blood in the perioperative period (Serretta et al., 2002; Varkarakis et al., 2004; Zargooshi, 2007). Thus **it may be prudent to have 1 or**

2 units of blood available intraoperatively for an open approach. For a robotic-assisted laparoscopic simple prostatectomy approach, type and screen is sufficient.

Finally, the patient must be informed of the benefits and risks associated with simple prostatectomy and written informed consent obtained. The benefit to be achieved is improved urination. **Potential risks include urinary incontinence, erectile dysfunction, retrograde ejaculation, UTI, injury to adjacent structures, bladder neck contracture, urethral stricture, and the need for a blood transfusion. Other potential untoward effects include deep vein thrombosis and pulmonary embolus. For a robotic or laparoscopic approach, open conversion also should be listed as a rare, yet potential, risk.**

Operating Day Preparation

The patient is placed on a clear liquid diet for 1 day before the procedure and self-administers an oral bowel preparation the day before the surgery. He is kept without oral intake after midnight and self-administers a Fleet enema the morning of surgery. The type of anesthesia to be used and the risks associated with it are discussed and finalized with the patient and his family in conjunction with the anesthesiologist. One dose of a second-generation cephalosporin is administered before making the incision. Sequential compression devices in the lower extremities are used to minimize the risk for deep vein thrombosis.

Surgical Technique

Anesthesia

The preferred anesthesia is general endotracheal anesthesia. Spinal or epidural anesthesia may be used only in an open approach when there is a medical or anatomic contraindication to general anesthesia or when the patient simply prefers regional anesthesia.

Open Simple Prostatectomy (Retropubic and Suprapubic Approach)

Proper Positioning of the Patient

Once anesthesia has been induced, the patient is positioned on the operating table in the supine position. If a cystoscopic examination is to be performed, the patient is prepared and draped in the usual manner for a transurethral diagnostic procedure. Flexible cystoscopy, in this situation, will obviate major repositioning of the patient. After the cystoscopy the table is placed in a mild Trendelenburg position without extension.

Incision and Development of the Space of Retzius

The suprapubic area is shaved, prepared, and draped in the usual sterile manner. A 22-Fr urethral catheter with a 30-mL balloon is passed into the bladder and connected to a sterile closed drainage system, and the balloon is inflated with 30 mL of saline. A lower midline incision from the umbilicus to the pubic symphysis is made. It is deepened through the subcutaneous tissue. **The linea alba is incised, allowing the rectus abdominis muscles to be separated in the midline. The transversalis fascia is incised sharply to expose the space of Retzius.** At the superior aspect of the wound, the posterior rectus abdominis fascia is incised above the semicircular line to the level of the umbilicus, and the peritoneum is mobilized cephalad starting at the pubic symphysis and swept anterolaterally. The pelvis is inspected for any abnormalities, and the inguinal area is examined for hernias. If a hernia is identified, it can be repaired using the preperitoneal approach (Schlegel and Walsh, 1987). A self-retaining Balfour retractor is placed in the incision and widened.

Retropubic Simple Prostatectomy

Exposure of the Prostate

A well-padded, malleable blade is connected to the Balfour retractor and used to displace the bladder posteriorly and superiorly. The anterior surface of the bladder and prostate are exposed. With the use of DeBakey forceps and Metzenbaum scissors, the preprostatic adipose tissue is gently removed to expose the superficial branch of the dorsal vein complex and the puboprostatic ligaments (Fig. 147.1).

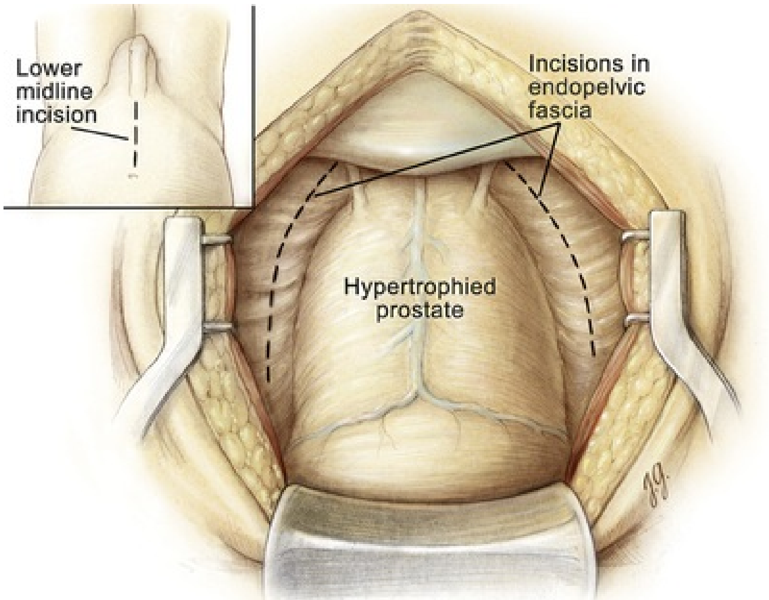

FIG. 147.1 Retropubic simple prostatectomy. The space of Retzius has been opened, and the periprostatic adipose tissue has been dissected free from the superficial branch of the dorsal vein complex. The endopelvic fascia is incised bilaterally *(dotted lines)*, and the puboprostatic ligaments are transected bilaterally. (© Brady Urological Institute.)

Hemostatic Maneuvers

Before proceeding with enucleation of the prostatic adenoma, it is important to achieve complete control of the dorsal vein complex and the lateral pedicles at the bladder neck (the main arterial blood supply to the prostate gland) (Walsh and Oesterling, 1990). To accomplish this task, the endopelvic fascia is incised laterally, and the puboprostatic ligaments are partially transected, similar to the maneuver in an anatomic radical retropubic prostatectomy (Reiner and Walsh, 1979). In patients with marked prostatic enlargement, this maneuver can be easier because the enlarged prostate gland protrudes out from beneath the pubic symphysis. A 3-0 Monocryl suture on a ⅝-inch circle-tapered needle is passed in the avascular plane between the urethra and the dorsal vein complex at the apex of the prostate and tied (Fig. 147.2A). The superficial branch of the dorsal vein at the bladder should be coagulated or ligated.

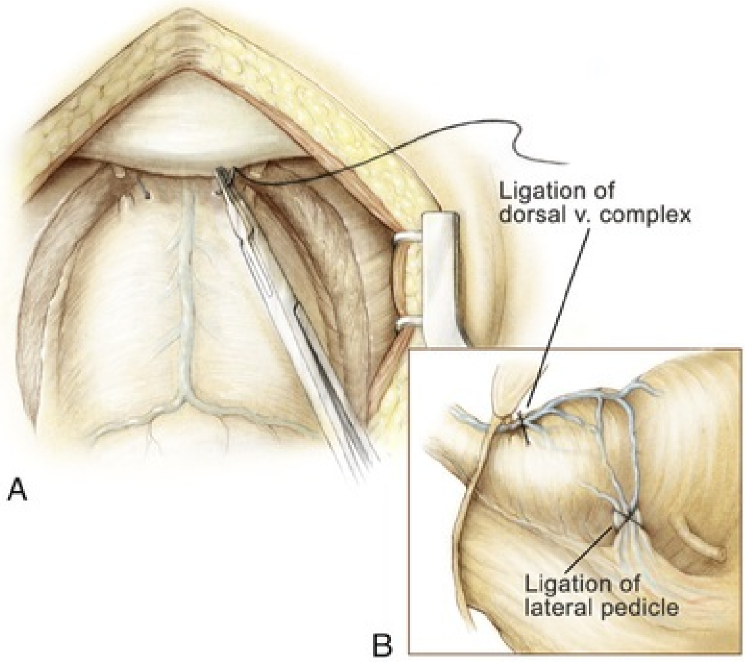

FIG. 147.2 Retropubic simple prostatectomy. (A) A 2-0 chromic suture on a ⅝-inch circle-tapered needle is passed in the avascular plane between the urethra and the dorsal vein complex at the apex of the prostate. A tie is grasped and tied around the dorsal vein complex. (B) With 2-0 chromic suture material on a CTX needle, a figure-of-eight suture is placed through the prostatovesicular junction just above the level of the seminal vesicles to control the main arterial blood supply to the prostate gland. When placing this suture, care must be taken to avoid entrapment of the neurovascular bundles located posteriorly and slightly laterally. (© Brady Urological Institute.)

At this point, attention is focused on securing the lateral pedicles at the prostatovesical junction. The 30-mL balloon of the catheter is used to identify the junction between the bladder and the prostate. The balloon is then deflated, and 2-0 chromic suture material on a large CTX needle is used to place a figure-of-eight suture deep into the prostatovesical junction at the level where the seminal vesicles approach the prostate gland bilaterally (see Fig. 147.2B). With this maneuver, the main arterial blood supply to the prostate adenoma is controlled. Having secured the dorsal vein complex earlier, the major sources of hemorrhage for this operation have been eliminated.

Enucleation of the Adenoma

With a sponge stick on the bladder neck to depress the bladder posteriorly, a No. 15 blade on a long handle is used to make a transverse capsulotomy in the prostate 1.5 to 2.0 cm distal to the bladder neck (Fig. 147.3). The superficial branch of the dorsal vein complex is transected as the transverse capsulotomy is made. It does not bleed because hemostasis of the dorsal vein complex has previously been controlled both proximally and distally. The incision is deepened to the level of the adenoma and extended sufficiently lateral in each direction to permit complete enucleation. A pair of Metzenbaum scissors is used to dissect the overlying prostatic pseudocapsule from the underlying prostatic adenoma. Once a well-defined plane is sufficiently developed, the index finger can be inserted between the prostatic adenoma and the pseudocapsule to further develop the plane laterally and posteriorly (Fig. 147.4). A pair of Metzenbaum scissors is then used to incise the anterior commissure from the bladder neck to the apex, separating the lateral lobes of the prostate anteriorly. The posterior prostatic urethra is exposed, and the index finger is inserted down to the verumontanum. The mucosa of the urethra overlying the left lateral lobe is divided sharply at the level of the apex under direct vision without injury to the external urinary sphincter. With the aid of a Babcock clamp, the left lateral lobe is removed safely. This maneuver is then repeated for the right lateral lobe. If a median lobe is present, the overlying mucosa is incised at the level of the bladder neck, and this lobe is removed (Fig. 147.5). In this manner, the entire prostatic adenoma is removed with preservation of a strip of posterior prostatic urethra. Because the capsulotomy was a transverse rather than longitudinal incision, there is little risk that the incision will be inadvertently extended into the sphincteric mechanism during the enucleation process, which would compromise subsequent urinary continence.

FIG. 147.4 Retropubic simple prostatectomy. (A) With blunt dissection with the index finger, the prostatic adenoma is dissected free laterally and

posteriorly. (B) Metzenbaum scissors are used to divide the anterior commissure to visualize the posterior urethra and verumontanum. (C) The index finger is then used to fracture the urethral mucosa at the level of the verumontanum. With this last maneuver, extreme care is taken not to injure the external sphincteric mechanism. (© Brady Urological Institute.)

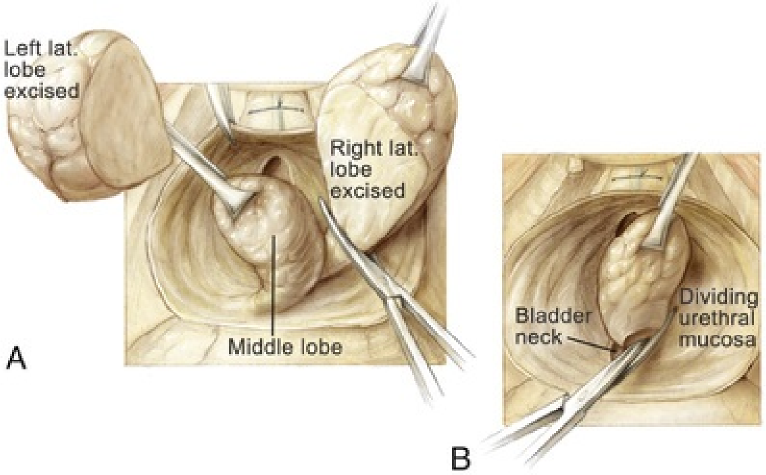

FIG. 147.5 Retropubic simple prostatectomy. (A) After removal of the left lateral lobe of the prostate, the right lateral lobe is excised with the aid of a tenaculum and Metzenbaum scissors. (B) Finally, the median lobe is removed under direct vision. (© Brady Urological Institute.)

The prostatic fossa is carefully inspected to ensure that all of the adenoma has been removed and that hemostasis is complete. **If hemorrhage is persistent, 4-0 chromic suture material can be used to place a figure-of-eight suture in the bladder neck at the 5- o'clock and 7-o'clock positions, as in suprapubic prostatectomy** (Fig. 147.6)**. When placing these sutures, it is necessary to visualize the ureteric orifices so that they are not incorporated.** Indigo carmine dye may be given intravenously to aid in the visualization of the ureteric orifices if necessary. If the bladder neck appears obstructive at the completion of the operation, it may be appropriate to perform a wedge resection at the 6-o'clock position and advance the bladder mucosa into the prostatic fossa.

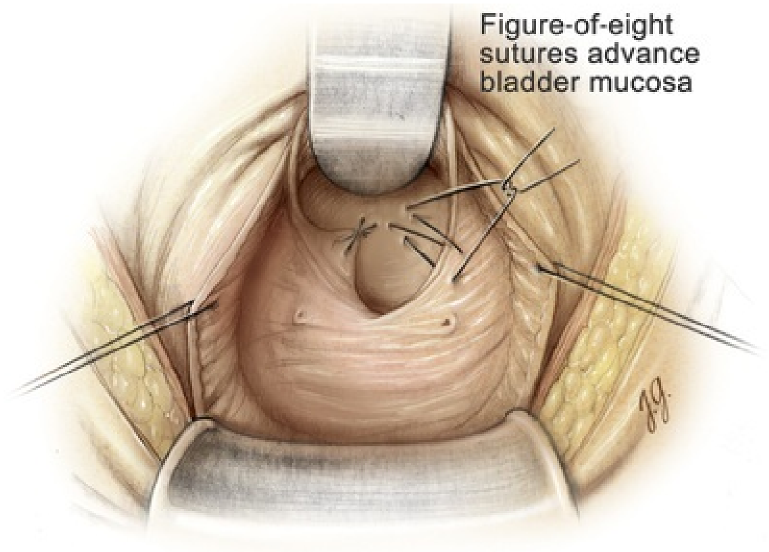

FIG. 147.6 Hemostatic maneuver during open simple prostatectomy. After enucleation of the entire prostatic adenoma, a 0-chromic suture is used to place two figure-of-eight sutures to advance bladder mucosa into the prostatic fossa at the 5-o'clock and 7-o'clock positions at the prostatovesicular junction to ensure control of the main arterial blood supply to the prostate. (© Brady Urological Institute.)

Suprapubic Simple Prostatectomy

Exposure of the Prostate

The anterior bladder wall is identified, and two 3-0 Vicryl stitches are placed on each side of the midline below the peritoneal reflection. A vertical cystotomy is made with electrocautery. With use of a pair of Metzenbaum scissors, a cystotomy is then extended cephalad and caudally to within 1 cm of the bladder neck. Several pairs of stay sutures are placed using 3-0 Vicryl on each side of the midline to facilitate exposure (Fig. 147.7). A figure-of-eight suture using 3-0 Vicryl is placed and tied at the most caudal position of the cystotomy to prevent further extension of the cystotomy incision during blunt finger dissection of the adenoma. Alternatively, a transverse bladder incision can be used. After inspecting the bladder, a well-padded, malleable blade is placed in the bladder, connected to the Balfour retractor, and used to retract the bladder cephalad. The bladder neck and prostate gland now can be visualized. A narrow Deaver retractor can be placed over the bladder neck and used to further expose the trigone. Indigo carmine dye may be given intravenously to aid in visualization of the ureteric orifices if necessary.

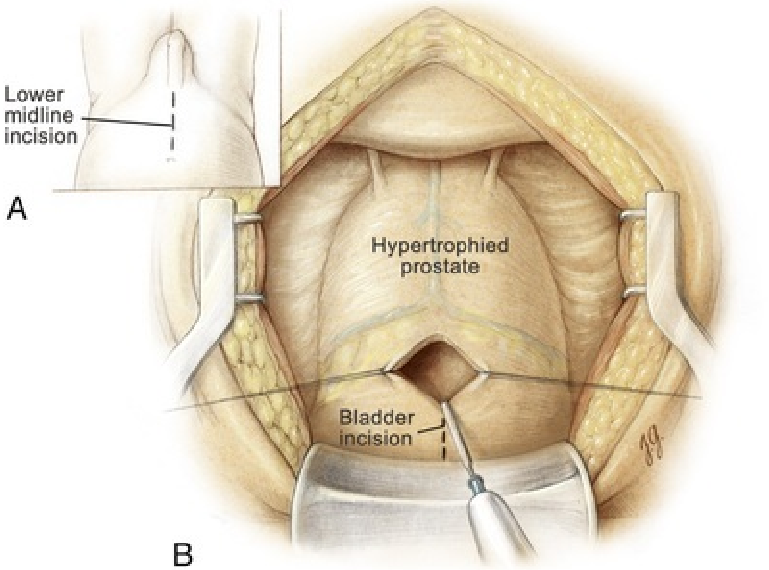

FIG. 147.7 Suprapubic simple prostatectomy. (A) A lower midline incision is made from the umbilicus to the pubic symphysis. (B) After developing the prevesical space, a small, longitudinal cystotomy is made with electrocautery. (© Brady Urological Institute.)

Enucleation of the Adenoma

Electrocautery is used to create a circular incision in the bladder mucosa distal to the trigone (Fig. 147.8). Care is taken not to injure the ureteric orifices. With use of a pair of Metzenbaum scissors, the plane between the prostatic adenoma and prostatic pseudocapsule is developed at the 6-o'clock position (Fig. 147.9). Once a well-established plane is created posteriorly, the prostatic adenoma is dissected circumferentially and inferiorly toward the apex, using blunt dissection (Fig. 147.10). At the apex, the prostatic urethra is transected using a pinch action of the two fingertips and avoiding excessive traction so as not to avulse the urethra and injure the sphincteric mechanism. At this point, the prostatic adenoma, either as one unit or separate lobes, can be removed from the prostatic fossa.

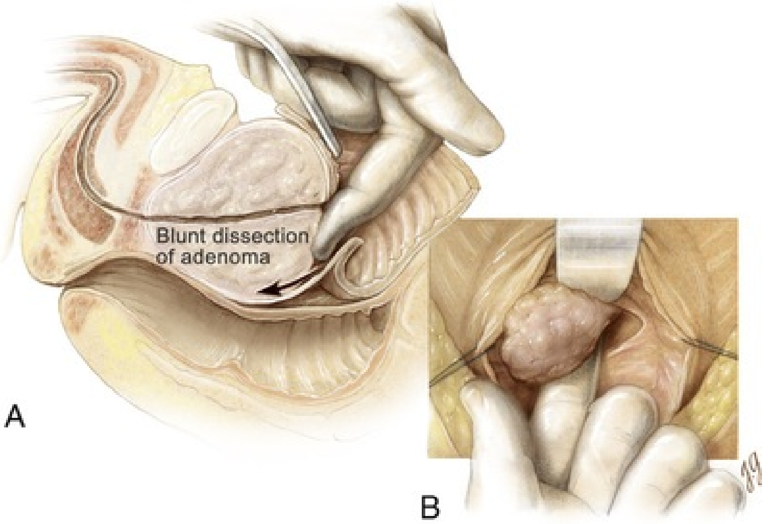

FIG. 147.10 Suprapubic simple prostatectomy. (A) Using the index finger, the prostatic adenoma is enucleated from the prostatic fossa *(lateral view).* (B) Anterior view of the same maneuver. With extremely large prostate glands, the left, right, and median lobes should be removed separately. (© Brady Urological Institute.)

Hemostatic Maneuvers

After enucleation of the adenoma, the prostatic fossa is inspected for residual tissue. If found, these nodules are removed by sharp or blunt dissection. The prostatic fossa also must be examined for discrete bleeding sites that frequently can be controlled with electrocautery or 4-0 chromic suture ligatures. In addition, a 0-chromic suture is used to place two figure-of-eight sutures to advance the bladder mucosa into the prostatic fossa at the 5-o'clock and 7-o'clock positions at the prostatovesical junction to ensure control of the main arterial blood supply to the prostate (see Fig. 147.6). With this maneuver, hemostasis is usually complete.

If hemorrhage remains pronounced despite the hemostatic sutures, a size 2 nylon purse-string suture can be placed around the vesical neck, brought out through the skin, and tied firmly, as described by Malament (1965). This maneuver closes the bladder neck and tamponades the prostatic fossa. The nylon suture is removed by cutting it at the skin and applying gentle traction on postoperative day 2 or 3. Plicating sutures can be placed transversely in the posterior prostatic pseudocapsule to prevent further bleeding, as described by O'Conor (1982).

Closure

After inspecting for complete adenoma removal and hemostasis, a 22-Fr, three-way Foley catheter with a 30-mL balloon is inserted through the anterior urethra and prostatic fossa into the bladder. Alternatively, a 22-Fr, two-way Foley catheter with a 30-mL balloon and a 20- to 24-Fr Malecot suprapubic tube are placed into the dome of the bladder. The suprapubic tube exits the bladder via a separate stab incision at the lateral aspect of the dome, avoiding the peritoneal cavity (Fig. 147.11). The suprapubic tube is secured with a 4-0 chromic purse-string suture.

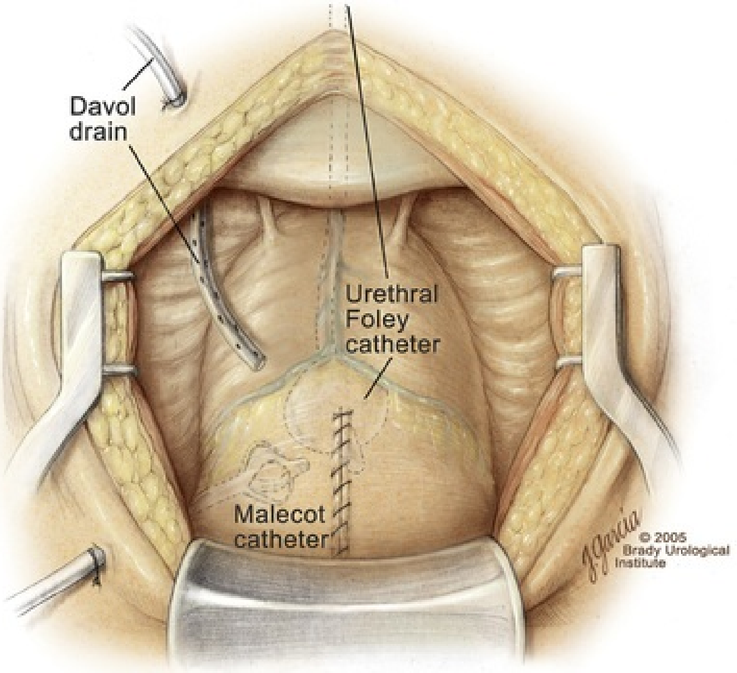

FIG. 147.11 Closure during suprapubic simple prostatectomy. After placement of a urethral catheter and a Malecot suprapubic tube, the cystotomy is closed in two layers using a running 2-0 Vicryl suture, enforced by tying multiple interrupted 3-0 Vicryl stay sutures. A closed Davol suction drain is placed on one side of the bladder and exits via a separate stab incision. (© Brady Urological Institute.)

In the suprapubic approach, with the urethral catheter in place, the prostatic pseudocapsule is closed (see Fig. 147.11) using 2-0 absorbable sutures. In the retropubic approach, the cystotomy incision is closed in two layers using 2-0 absorbable sutures (Fig. 147.12).

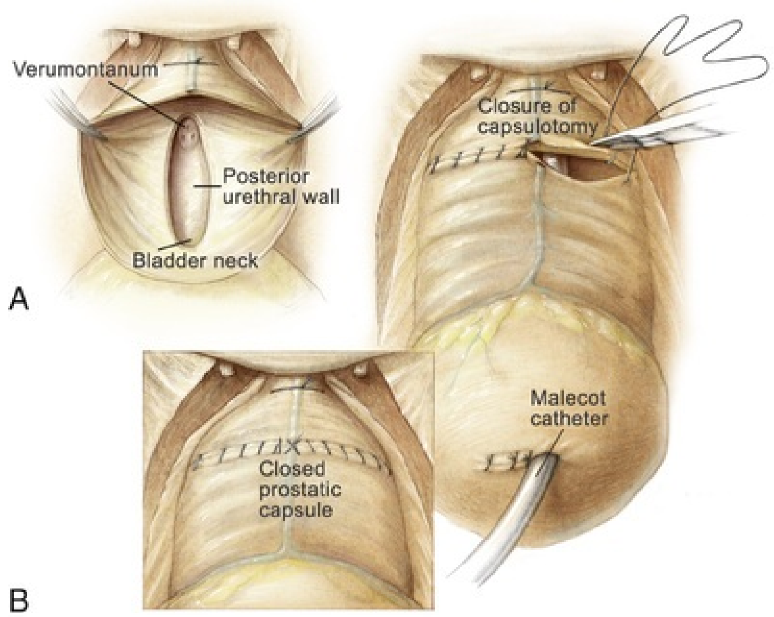

FIG. 147.12 Closure during retropubic simple prostatectomy. (A) View of the prostatic fossa and posterior urethra after enucleation of all the prostatic adenoma. Note that the verumontanum and a strip of posterior urethra remain intact. (B) After placement of a urethral catheter and, if needed, a Malecot suprapubic tube, the transverse capsulotomy is closed with two running 2-0 chromic sutures. The two sutures are tied first to themselves and then to each other across the midline to create a watertight closure of the prostatic pseudocapsule. (© Brady Urological Institute.)

Fifty milliliters of water is then placed in the balloon to ensure the Foley catheter balloon remains in the bladder and does not retract into the prostatic fossa. The bladder is then irrigated with saline to ensure continued hemostasis and test the closure for leakage. A small closed-suction drain is placed via a separate stab incision lateral to the prostate and bladder on one side to prevent hematoma and urinoma formation. The pelvis is irrigated with copious amounts of normal saline solution, and the rectus fascia is reapproximated with a size 1 polydioxanone (PDS) suture on a needle in a running fashion. The skin is closed with skin staples or 4-0 absorbable suture. The drain is secured to the abdominal wall, and the urethral catheter is secured to the lower extremity.

Postoperative Management

In the recovery area, the outputs from the pelvic drain and urethral catheter are monitored. In addition, it is routine to verify the hematocrit. If significant hemorrhage is noted, the urethral catheter may be placed on traction so that the balloon containing 50 mL of saline can compress the bladder neck and prostatic fossa. Constant and reliable traction can be maintained by securing the catheter to the abdomen. In addition, continuous bladder irrigation can be initiated to prevent clot formation. For most patients these measures are adequate and effective. However, if excessive bleeding persists after these measures, the urethral catheter can be removed in the operating suite and a cystoscopic inspection of the prostatic fossa and bladder neck can be performed to identify and fulgurate discrete bleeding sites. If marked hemorrhage continues to persist, re-exploration should be strongly considered.

On the evening of the day of surgery, the patient is asked to perform the dorsiflexion and plantarflexion exercises while awake and perform pulmonary exercises. Effective pain management consists of intravenous opioids by a patient-controlled analgesic pump.

On the first postoperative day, the patient is started on a gradually advancing diet and asked to ambulate four times per day. Pulmonary exercises are continued. If the hematuria is resolved, continuous bladder irrigation can be discontinued with a urethral catheter (and suprapubic tube, if present) placed for gravity drainage. Also, the balloon in the urethral catheter is partially deflated to 30 mL of saline, and residual clots are removed by irrigation.

On the second postoperative day, if urine is clear and both a suprapubic tube and a urethral catheter were placed intraoperatively, the urethral catheter may be removed, and the suprapubic tube is clamped to allow a voiding trial. The patient is encouraged to ambulate and continue pulmonary exercises. When the patient tolerates a regular diet, oral analgesics can be given and parenteral opioids discontinued. Appropriate discharge instructions are reviewed with the patient at this time in preparation for discharge on the second day after surgery. The pelvic drain is removed if the drainage is low. Pathologic examination of the enucleated prostatic adenoma should be performed.

On discharge from the hospital, the patient is encouraged to gradually increase his activity. If the patient has a clamped suprapubic tube and voids well with a minimal postvoid residual urine volume, the suprapubic tube is then removed in the clinic 1 week after surgery. If only the urethral catheter was used without a suprapubic tube, it is removed in the clinic 1 week after surgery. The patient should be able to resume full activity 3 to 4 weeks postoperatively with outpatient visits at 6 weeks and 3 months.

Robotic-Assisted Laparoscopic Simple Prostatectomy (Video 147.1)

Proper Positioning of the Patient

Positioning of the patient for this procedure is same as that for robotic-assisted laparoscopic radical prostatectomy. After general endotracheal anesthesia has been induced, the patient is positioned in the supine position on the operating table. Both arms are padded and tucked to the side. The legs are placed in the low lithotomy position in a spreader bar. The patient is secured to the operative table at the level of the shoulders with heavy cloth tape. The lower abdomen is shaved, prepared, and draped in the usual sterile manner. A 16-Fr urethral catheter is passed into the bladder and connected to a sterile closed drainage system. The balloon is inflated with 10 mL of saline. The operative table is placed in the maximum Trendelenburg position.

Abdominal Access, Insufflation, and Trocar Placement

The transperitoneal approach is favored over the extraperitoneal approach because of the greater working space in the setting of a massively enlarged prostatic adenoma. Intraperitoneal access is obtained with a Veress needle through an umbilical puncture site. After adequate insufflation at 15 mm Hg, the peritoneal cavity is entered through a vertical supraumbilical incision using a 12-mm bladeless trocar followed by confirmation of the proper placement with a robotic camera. Alternatively, the initial entrance can be achieved using the Visiport device and 0-degree lens and camera. Adhesions are lysed laparoscopically, if present. One additional 12-mm trocar is placed on the right side, then three 8-mm robotic trocars are placed bilaterally (two on the left, one on the right), and then one additional 5-mm trocar is placed on the right side, all under direct vision. The da Vinci Robotic System is then docked. Typically, three robotic instruments are used (fenestrated bipolar forceps and ProGrasp forceps on the left side and monopolar scissors on the right side).

Development of the Space of Retzius

The anterior peritoneum is taken down lateral to the medial umbilical ligaments to displace the bladder posteriorly. Applying posterior and cephalad traction on the urachus, the space of Retzius is developed using both blunt and sharp dissection. Periprostatic adipose tissue is then removed. Endopelvic fascia is taken down carefully to expose the prostatic contour. Control of the deep dorsal vein complex or prostatic lateral pedicles is not necessary.

Bladder Neck Incision

The anterior bladder neck is divided transversely using monopolar scissors until the urinary catheter is visualized. After identifying the catheter, it is grasped by an assistant or the fourth robotic arm with ProGrasp forceps and pulled anteriorly before widening the bladder neck incision. **To better visualize the intravesical component of the prostate and the trigone, the bladder neck incision in this approach should be wider and more cephalad compared with the narrow incision at the vesicoprostatic junction in a typical robotic-assisted laparoscopic radical prostatectomy.** When a large median lobe is encountered, it is lifted anteriorly by the assistant or the ProGrasp forceps. Bilateral ureteric orifices are identified to avoid inadvertent injury.

Enucleation of the Adenoma

Electrocautery of the robotic monopolar scissors is used to create a circular incision in the bladder mucosa distal to the trigone. Care is taken not to injure the ureteric orifices. With the use of monopolar scissors, the subcapsular plane between the prostatic adenoma and prostatic pseudocapsule is developed initially at the 6-o'clock position to prevent inadvertent injury to ureteral orifices. **While developing the plane between the prostatic adenoma and pseudocapsule, it is crucial to have an experienced assistant or the robotic fourth arm with forceps to optimize the visualization of the dissection plane and provide traction. Compared with the open simple prostatectomy approach, the dissection plane should be better visualized at all times during this procedure.** Once a well-established plane is created posteriorly, the prostatic adenoma is dissected circumferentially and inferiorly toward the apex, using both blunt dissection and limited electrocautery. At the apex, the prostatic urethra is transected while avoiding excessive traction. At this point, the prostatic adenoma, either as one unit or separate lobes, can be removed from the prostatic fossa and set aside.

Hemostasis and Vesicourethral Anastomosis

The prostatic fossa is carefully inspected, and hemostasis is achieved by limited electrocautery or suture ligatures. The vesicourethral anastomosis is performed continuously with 2-0 barbed sutures in a single-knot method (Van Velthoven et al., 2003). A 20-Fr, two-way Foley catheter is inserted. A watertight closure is confirmed using normal saline irrigation by Foley catheter. A closed-suction pelvic drain is placed through the lateral 8-mm robotic trocar site and secured to the skin.

Adenoma Extraction and Closure

Hemostasis is reconfirmed with lower insufflation pressure (<10 mm Hg). The prostatic adenoma is placed inside of the entrapment bag and extracted through extension of the supraumbilical trocar site. The rectus abdominis fascial defect of the extraction incision is closed using No. 1 PDS in a figure-of-eight fashion. The skin edges are reapproximated using 4-0 Biosyn subcuticular suture.

Postoperative Management

Postoperative management after robotic-assisted laparoscopic simple prostatectomy is similar to that after open simple prostatectomy. However, continuous bladder irrigation and blood transfusion are less frequently used after robotic-assisted laparoscopic simple prostatectomy.

On discharge from the hospital, the patient is encouraged to gradually increase his activity. A Foley catheter is removed in the clinic 1 week after surgery.

Complications of Simple Prostatectomy

The overall rate of morbidity and mortality associated with simple prostatectomy is extremely low. Historically, excessive hemorrhage had been a major concern. But with modern surgical techniques, blood loss is now minimal and the need for a blood transfusion is uncommon (Zargooshi, 2007). In retropubic simple prostatectomy, controlling the dorsal vein complex distal to the apex of the prostate and ligating the lateral pedicles to the prostate at the prostatovesical junction markedly reduces venous and arterial bleeding, respectively. Nevertheless, it may still be prudent to have 1 to 2 units of autologous blood available at the time of open simple prostatectomy. **In laparoscopic simple prostatectomy with or without robotic assistance, pneumoperitoneum significantly decreases the perioperative hemorrhage and almost eliminates the need for blood transfusion.**

Urinary extravasation can be of concern in the immediate postoperative period; this most likely results from incomplete closure of the prostatic capsulotomy in retropubic simple prostatectomy or the cystotomy in suprapubic simple prostatectomy and robotic-assisted laparoscopic simple prostatectomy. This usually resolves spontaneously with continued catheter drainage. The drain should be left in place until urinary extravasation ceases.

After a simple prostatectomy, urgency and urgency incontinence may be present for several weeks to several months, depending on the preoperative bladder status. If the condition is severe, the patient may be given an anticholinergic agent such as oxybutynin (Ditropan). Stress incontinence and total incontinence are rare. With precise enucleation of the prostatic adenoma, risk for injury to the external sphincter mechanism is minimal. If stress incontinence does result after the procedure, the patient may benefit from transurethral collagen injections for a mild condition or an artificial urinary external sphincter when the situation is more severe.

Late urologic complications are not common. Acute cystitis rarely occurs as long as the patient voids to completion. Acute epididymitis can occur occasionally if infected urine refluxes into the ejaculatory ducts.

Erectile dysfunction occurs in 3% to 5% of patients undergoing a simple prostatectomy; it is more common in older men than in younger men. Retrograde ejaculation occurs in 80% to 90% of patients after surgery. Also, 2% to 5% of patients develop bladder neck contracture 6 to 12 weeks after open simple prostatectomy (Tubaro et al., 2001; Varkarakis et al., 2004). If bladder neck contracture develops, initial management should be dilation with urethral sounds or a direct vision incision of the bladder neck using a Collings knife to create a 22-Fr opening.

The most common nonurologic adverse effects include deep vein thrombosis, pulmonary embolus, myocardial infarction, and a cerebrovascular event. The incidence of any one of these complications is less than 1%, and the overall mortality rate resulting from this operation should approach zero (Varkarakis et al., 2004).

Summary

Simple prostatectomy, whether performed by an open retropubic or suprapubic approach or a robotic-assisted laparoscopic approach, is an excellent treatment option for (1) men with symptomatic bladder outlet obstruction as a result of benign prostatic hyperplasia causing a markedly enlarged prostate gland, (2) individuals with a concomitant bladder condition, such as a bladder diverticulum or large bladder calculi, and (3) patients who cannot be placed in the dorsal lithotomy position for TURP. With improved surgical technique, these procedures can be routinely performed in a precise manner with minimal hemorrhage. Efficacy, in terms of durable improvement in symptom score and peak urinary flow rate, is superior to other treatment options available for the obstructing prostate gland, including TURP. Meanwhile, complications are minimal, and the length of hospitalization has been markedly reduced. For most patients, the length of hospital stay is 2 days or less. Thus, for the properly selected individual, a simple prostatectomy is a highly effective and well-tolerated operation.

Key Points

- Simple prostatectomy should be considered when the obstructive tissue is estimated to weigh more than 75 g or sizable bladder diverticuli or calculi exist.
- Before performing a simple prostatectomy, the presence of significant prostate cancer should be determined.
- Potential risks of simple prostatectomy include urinary incontinence, erectile dysfunction, retrograde ejaculation, UTI, bladder neck contracture, urethral stricture, deep vein thrombosis, pulmonary embolus, and the need for blood transfusion.
- Advantages of simple prostatectomy over TURP are a lower retreatment rate, more complete removal of the prostatic adenoma under direct vision, and no risk for TUR syndrome.
- Disadvantages of open simple prostatectomy over TURP are a lower midline incision, longer hospitalization, and increased potential for

perioperative hemorrhage.

- Compared with open simple prostatectomy, robotic-assisted laparoscopic simple prostatectomy can be performed with smaller incisions with shorter hospital stay and decreased risk for perioperative hemorrhage and blood transfusion.
- Two approaches to open simple prostatectomy are retropubic and suprapubic.
- Compared with the retropubic approach, suprapubic prostatectomy is ideal for men with a large median lobe, clinically significant bladder diverticulum, or large bladder calculi.

Epidemiology, Etiology, and Prevention of Prostate Cancer

Andrew J. Stephenson MD, MBA, FRCSC, FACS, Robert Abouassaly MD, MS, Eric A. Klein MD

Epidemiology

Incidence and Mortality Trends

Incidence

Prostate cancer has been the most common noncutaneous malignancy in US men since 1984, now accounting for 19% of all such cancers (Fig. 148.1) (American Cancer Society, 2017)**. Among men alive today, it is estimated that approximately 1 in 8 (12.9%) will be diagnosed with prostate cancer, and 1 in 40 (2.5%) will die from this disease** (American Cancer Society, 2017)**. Prostate cancer incidence varies by race/ethnicity, with African-Americans experiencing a 73% higher incidence rate than whites (Table 148.1)** (Siegel et al., 2014). Incidence rates for prostate cancer have changed substantially over the past 25 years. The incidence rate rose by approximately 2% per year from 1975 to the late 1980s, related in part to the incidental detection of prostate cancer associated with the use of TURP for benign prostatic hyperplasia (Potosky et al., 1990). The incidence of prostate cancer rose dramatically from 1989 to 1992 after the introduction of the prostate-specific antigen (PSA) screening test (with approval from the U.S. Food and Drug Administration [FDA] for early diagnosis in 1992), declined sharply from 1992 to 1995, and generally decreased from 2000 to 2013, with a marked drop between 2011 and 2012 (see Fig. 148.1), reflecting changes in screening practices (American Cancer Society, 2017; Jemal et al., 2015). **The precipitous fall in incidence between 1992 and 1995 has been attributed to the “cull effect” of identifying previously unknown cancers in the population by the use of PSA, followed by a return to baseline incidence rates** (Stephenson et al., 1996). For 2019, an estimated 174,650 new cases of prostate cancer will be diagnosed in the United States, and the age-adjusted incidence rate is 109.2 per 100,000 men per year (American Cancer Society, 2017).

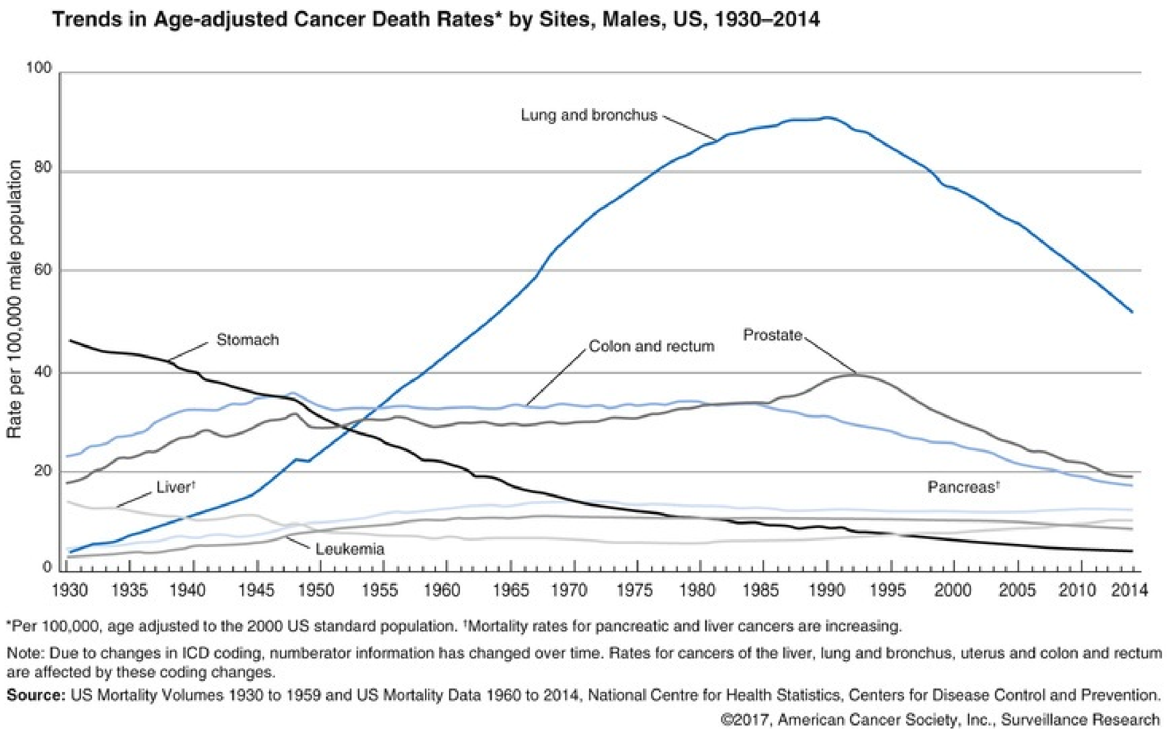
Mortality

Prostate cancer mortality rates in the United States rose slowly between 1973 and 1990 (Fig. 148.2). This may have resulted from a gradual increase in the number of biologically lethal cancers or a decreasing use or effectiveness of therapy during this interval. In the early 1990s, an abrupt rise in mortality was observed. This increase was likely caused by an increase in attribution bias occurring when the National Center for Health Statistics made a change from manual to automated methods for assignment of cause of death (Feuer et al., 1999). **Subsequent to 1991, the peak mortality year, steady declines in prostate cancer mortality were reported in both Caucasians and African-Americans at an average rate of 4.1% per year. The magnitude of this decline is nearly 2.5 times larger than the increase in mortality seen as a result of attribution bias, so it seems likely that the observed declines since 1991 are real and clinically significant** (Stephenson et al., 2005). Prostate cancer is the third-leading cause of cancer death in the United States, accounting for 8% of all such events. In 2019, an estimated 31,620 men will die from prostate cancer in the United States, for an approximate annual rate of 19.2 per 100,000 population, representing a 48% decrease from the 1991 peak (American Cancer Society, 2017). **Furthermore, the mortality rate for prostate cancer in Caucasians in the United States has declined to a level lower than that observed before the introduction of PSA-based screening in 1987** (Tarone et al., 2000). As the natural history of progressive prostate cancer is protracted relative to other common solid malignancies, it is associated with the fewest expected years of life lost, estimated at 5.9 and 1.8 years for clinically detected and screen-detected cancers, respectively (Liu et al., 2013; Friman et al., 1989). **Prostate cancer was the leading single cause of death (35%) among those diagnosed with this disease between 1973 and 2008 in the U.S. Surveillance, Epidemiology, and End Results (SEER) program, but these men were still more likely to die from other causes** (Epstein et al., 2012).



*Per 100,000, age adjusted to the 2000 US standard population. †Mortality rates for pancreatic and liver cancers are increasing.

Note: Due to changes in ICD coding, numberator information has changed over time. Rates for cancers of the liver, lung and bronchus, uterus and colon and rectum are affected by these coding changes.

FIG. 148.2 Data from Trends in Cancer Death Rates for Men, United States, 1930–2014. (American Cancer Society, 2017).

The observed decline in mortality since 1991 may be a result of (1) early detection and stage migration from PSA screening, (2) increased utilization and effectiveness of curative treatments, (3) changes in the attribution of cause of death, (4) improvements in therapy for advanced disease, or (5) increased risk for death from secondary causes among men receiving prostate cancer therapy (Tarone et al., 2000). The initial decline in mortality appears to have occurred too soon after the introduction of the PSA test to be attributable to screening (Etzioni et al., 1999). One hypothesis is that it is the result of the more aggressive treatment of prostate cancer that began in the 1980s (Walsh, 2000). Indeed, the vast majority of men diagnosed with prostate cancer since 1986 have received curative-intent therapy at rates that are double that observed before 1986 (Etzioni et al., 2008; Welch and Albertsen, 2009). Using mathematical models under some assumptions, it is estimated that up to one-third of the observed decline in mortality may be caused by changes in treatment approaches to prostate cancer (i.e., increased use of surgery and radiation), whereas the remainder is thought to be caused by other interventions, such as prostate-specific antigen screening and advances in the treatment of recurrent and progressive disease (Etzioni et al., 2012).

Racial Differences

African-Americans and Jamaicans of African descent have the highest incidence of prostate cancer in the world, although incidence rates have been decreasing at a similar rate to Caucasians, at least in part resulting from a recent decrease in PSA testing (American Cancer Society, 2017; Houston et al., 2018)**. Although African-Americans have experienced a greater decline in mortality than Caucasians since the early 1990s, their death rates are still 2.3 times higher.**

Many biologic, environmental, and social hypotheses have been advanced to explain these differences, ranging from postulated differences in genetic predisposition; differences in mechanisms of tumor initiation, promotion, and/or progression; higher-fat diets, higher serum testosterone (T) levels, or higher body mass index (BMI); structural, financial, educational, and cultural barriers to screening, early detection, and aggressive therapy; and physician bias. Models of prostate cancer natural history in African-Americans suggest that their observed incidence patterns implicate higher incidence of preclinical disease and higher risk for metastatic progression (Tsodikov et al., 2017a). **Additionally, differences in treatment patterns by race have consistently shown that African-Americans at every stage get less aggressive therapy regardless of age, marital status, tumor risk, and comorbidities status compared with Caucasians, even within equal-access health care systems** (Gross et al., 2008; Hoffman et al., 2003; Klabunde et al., 1998; Moses et al., 2016; Nambudiri et al., 2012; Presley et al., 2013; Shavers et al., 2004). Among men 67 to 84 years of age in the SEER-Medicare dataset, the racial disparity between African-Americans and Caucasians was highest (OR 0.57, 95% CI, 0.48 to 0.68) among those most likely to benefit (life expectancy greater than 10 years, Gleason 7 to 10, or clinical stage T2b to T2c (Presley et al., 2013). **However, prostate cancer mortality among African-Americans and Caucasians is similar in equal-access health care systems** (Graham-Steed et al., 2013)**. There are currently no data that clearly indicate if any of these hypotheses account for observed differences in incidence or mortality, and it seems likely that the source of the disparity is multifactorial, although recent molecular data indicate biologic differences are at least in part responsible** (see the Etiology and Molecular Genetics section later in this chapter).

The incidence of prostate cancer in other ethnic groups is lower than that of Caucasians and African-Americans (see Table 148.1). Interestingly, men of Asian descent living in the United States have a lower incidence compared with white Americans, but their risk is higher than that of men of similar backgrounds living in Asia (Haenszel et al., 1968; Yu et al., 1991). Likewise, Japanese immigrants have an incidence more comparable to men of similar ancestry born in the United States than to those living in Japan (Shimizu et al., 1991). Conversely, US-born blacks have a lower incidence of prostate cancer than sub-Saharan African-born blacks (Moses et al., 2016). These data implicate external factors (dietary, lifestyle, environmental) in the development of prostate cancer.

Global Incidence and Mortality

Prostate cancer is the second most common cancer and the fifth leading cause of cancer deaths worldwide, with an estimated 1.1 million new cases and 300,000 deaths in 2012 (World, 2014)**. By 2030, these rates are anticipated to increase to 1,700,000 and 499,000 as a result of global population growth and increased life expectancy. Prostate cancer incidence rates vary by 25-fold worldwide, primarily resulting from differences in screening practices, although the westernization of lifestyle has also been suggested as a possible explanation** (Hsing et al., 2000)**. The highest incidence rates are in Australia and New Zealand (111.6 per 100,000), northern and western Europe, and North America, and the lowest are in Asia and Northern Africa** (World, 2014). Incidence rates increased dramatically in the 1990s in many of the highest-resource countries as PSA testing became available. Although incidence rates have leveled off in some of these countries, they continue to uniformly increase in countries transitioning toward higher levels of human development (Zhou et al., 2016). Prostate cancer mortality rates varied 10-fold with the highest age-adjusted rates per 100,000 men in the Caribbean (26.3), Sub-Saharan Africa (18.3 to 19.3), and South America (16.2), and the lowest rates in Asia (3.1) (Center et al., 2012). Mortality rates have been decreasing since the 1990s in some of the highest-resource countries, such as the United States (–4.3%), Canada (–3.1%), Western Europe (–2.3 to –4%), Australia (–2.3%), and New Zealand (–2.8%), likely as a result of improved treatment and/or PSA screening (Collin et al., 2008). However, increasing prostate cancer mortality was seen among nations of central and eastern Europe, Asia, and Africa. Prostate cancer is the most common cancer among Sub-Saharan Africans, with a mortality rate more than 5 times higher than in African-Americans (Gronberg et al., 2003; Rebbeck et al., 2013). In general, there appears to be a positive correlation between the human development index (HDI, composite index composed of life expectancy, education, gross national income per capita, health, and living standard) and prostate cancer incidence rates. However, there is a negative correlation between the HDI and standardized mortality rates (Khazaei et al., 2016). **Using data from population-based cancer registries, the CONCORD study found that age-standardized 5-year survival rates vary greatly, ranging from greater than or equal to 80% in the United States, Australia, and Canada to less than 40% in Denmark, Poland, and Algeria, suggesting local influences on detection and therapy** (Coleman et al., 2008).

Age at Diagnosis

Prostate cancer is rarely diagnosed in men younger than 50 years of age, accounting for only 2% of all cases (Jani et al., 2008)**, however, this is highly correlated with age at first screening** (Godtman et al., 2016)**. Before the PSA era, the median age at diagnosis was 70, falling to 67 over the past decade, with 63% diagnosed after 65 years of age** (Ries et al., 2008). Patients with familial prostate cancer, or germline mutations increasing susceptibility to prostate cancer (e.g., *BRCA2* mutation), tend to be diagnosed at an earlier age compared with men with sporadic prostate cancer (Brandt et al., 2009; Gleicher et al., 2016; Plonis et al., 2015). The incidence rate in 2005 relative to 1986 (the year before PSA was commercially available) was 0.56 in men ≥ 80 years of age, 1.09 in those 70 to 79 years, 1.91 in those 60 to 69 years, 3.64 in those 50 to 59 years, and 7.23 in men younger than 50 years of age (Welch and Albertsen, 2009). **This reflects a shift in diagnosis to an increasingly younger population after the introduction of PSA, with important implications for deciding on the need for and type of therapy.** Although age-specific incidence rates decline after 70 years of age, the risk for prostate cancer death increases throughout life. **The average age of death from prostate cancer is 77 years of age and has remained stable over the past three decades** (Epstein et al., 2012)**, however, men with familial prostate cancer, on average, die at an earlier age than men without a family history of prostate cancer** (Brandt et al., 2009).

Stage at Diagnosis

In addition to changes in incidence and mortality over the past several decades, there has been a substantial shift to more favorable stage at presentation of newly diagnosed disease. **This clinical stage migration is largely if not**

exclusively accounted for by PSA screening (Catalona et al., 1993; Mettlin et al., 1993)**. Since the introduction of PSA testing, 81% of newly diagnosed men have localized disease, whereas the incidence of metastatic disease has decreased by 75%** (Newcomer et al., 1997). Nonpalpable cancers (AJCC clinical stage T1c) now account for 60-75% of newly diagnosed disease (Gallina et al., 2008). Clinical stage migration has also been associated with improvements in 5-year disease-specific survival, which is 99.2% overall and 28% for men with advanced disease (Siegel et al., 2014).

The use of PSA has also resulted in a substantial downward pathologic stage migration as evidenced by an increase in the proportion of patients with organ-confined disease (Catalona et al., 1993; Jhaveri et al., 1999) **and a decrease in the proportion with seminal vesicle involvement** (Gallina et al., 2008). Since 1995, however, a slowing in this trend has been observed, suggesting a diminishing effect of PSA screening on pathologic stage migration (Dong et al., 2007).

Effect of Screening on Incidence and Mortality

The use of PSA as a screening test has had the greatest impact on the incidence and potentially mortality of prostate cancer worldwide. Since the introduction of the PSA test, lifetime risk for prostate cancer in the United States has nearly doubled from 7.8% to 12.9%, and the risk for dying from this disease has decreased from 3% to 2.5% (American Cancer Society, 2017). In the **Prostate Cancer Prevention Trial (PCPT),** 14% of men in the placebo arm were diagnosed by annual PSA screening within 7 years of enrollment (Thompson et al., 2003), suggesting that lifetime risk for regular screening may approach 20% (Boyle et al., 2009).

Recently, the results of two large randomized trials assessing the effect of PSA screening on prostate cancer mortality were published. The U.S. Prostate, Lung, Colorectal, and Ovarian (PLCO) cancer screening trial reported on 76,685 US men 55 to 74 years of age randomized between annual screening or usual care (Andriole et al., 2012). **Through 15 years of follow-up, there was no difference in prostate cancer mortality between the groups (47.8 vs. 46.0 deaths per 100,000 person-years in the screening and control groups, respectively; HR 1.03; 95% CI, 0.87 to 1.23)** (Pinsky et al., 2017)**. The trial has been criticized for high rates of contamination, with an estimated 90% of patients in the control arm having received at least one PSA before or during the trial** (Shoag et al., 2016). Thus, the trial did not fairly compare annual screening versus none and has been more accurately described as a comparison of organized screening versus opportunistic screening. **A recent reanalysis of the PLCO trial comparing those screened versus those not screened (rather than on an intent-to screen basis) suggested a 25% to 30% reduction in prostate-cancer–specific mortality in those screened** (Tsodikov et al., 2017a). The European Randomized Study of Screening for Prostate Cancer (ERSPC) included 162,243 men between 55 and 69 years of age randomized between PSA screening every 4 years or no screening (Schröder et al., 2014). **After a median follow-up of 13 years, men in the screening arm had a 57% (95% CI, 51 to 62) increased incidence of prostate cancer compared with controls and a 21% (95% CI, 9 to 31) relative reduction in death from prostate cancer (4.3 vs. 5.4 cancer deaths per 10,000 person-years). Models based on these two trials estimate a reduction in prostate cancer mortality of 37% to 43% under annual screening with 100% attendance and biopsy compliance and no contamination** (de Koning et al., 2018).

Soon after publication of the PLCO and ERSPC, the U.S. Preventive Services Task Force (USPSTF) in 2012 recommended against routine PSA screening in healthy men regardless of age, race, or family history. It gave PSA a grade D recommendation, meaning that there was a moderate-to-high certainty that the service has no net benefit or that the harms outweigh the benefits (Moyer et al., 2012). The early impact of these recommendations on clinical practice, and the epidemiology of the disease, have been examined in several publications (Lee et al., 2017). Data from self-reported PSA screening demonstrated an up to 55% relative reduction in prostate cancer screening across all age groups, whereas data from electronic medical records and administrative claims showed modest to no reductions in screening in men younger than 70 years of age. Studies have also demonstrated up to 40% relative reductions in prostate biopsies and a 16% reduction in the number of prostatectomies performed per urologist (Halpern et al., 2017). Further, data from the SEER and the National Cancer Database suggest a nearly 30% decrease in the incidence of prostate cancer in the years after the USPSTF recommendations (Barocas et al., 2015; Jemal et al., 2015), with observed decreases in low-, intermediate-, and high-risk disease (Herget et al., 2016). Modeling studies suggest that if screening for prostate cancer were abandoned entirely, there would be an estimated 46% to 57% increase in metastatic cases at presentation, leading to as much as a 20% increase in prostate cancer deaths. However, it is too early to determine the actual impact of changes in USPSTF recommendations on prostate cancer incidence and mortality. **In April 2017, the USPSTF partially reversed its course and submitted new draft recommendations, giving a grade of C to prostate cancer screening in men 55 to 69 years of age (offered for selected patients), but keeping the grade of D for men 70 years of age and older (discouraging its use). In doing so, the task force acknowledged the limitations of the PLCO with respect to PSA contamination in the nonscreened arm, the marked mortality reduction in those screened in the ERSPC, and the growing adoption of active surveillance in men with low-risk disease leading to less overtreatment of PSA-detected nonlethal cancers.** How the new recommendations will affect prostate cancer incidence and mortality remains to be determined.

Risk Factors

Considerable evidence suggests that **both genetics and environment play a role in the origin and evolution of prostate cancer.** Traditional and molecular epidemiology and newer genome-based techniques have identified a number of potential risk factors associated with the development of prostate cancer.

Familial and Germline Genetic Influences

Epidemiologic and molecular evidence suggests that prostate cancer has as strong familial component as demonstrated by epidemiologic studies and germline genetic analysis. The inherited risk for prostate cancer has been estimated to be as high as 60% (Hjelmborg et al., 2014). It is believed that between 5% and 10% of prostate cancer cases are primarily caused by high-risk inherited genetic factors or prostate cancer susceptibility genes (PDQ Cancer Genetics Editorial Board, 2002). A family history of a brother or father with prostate cancer increases the risk for prostate cancer, and the risk is inversely related to age at diagnosis of the relative. **Generally, relative risk increases according to the number of affected family members, their degree of relatedness, and the age at which they were affected** (Table 148.2) (Zeegers et al., 2003).

TABLE 148.2

Family History and Risk for Prostate Cancer

FAMILY HISTORY	RELATIVE RISK	95% CONFIDENCE INTERVAL
Father affected at any age	2.35	2.02–2.72
Brother(s) affected at any age	3.14	2.37–4.15
One affected first-degree relative diagnosed at any age	2.48	2.25–2.74
Affected first-degree relatives diagnosed <65 years	2.87	2.21–3.74
Affected first-degree relatives diagnosed ≥65 years	1.92	1.49–2.47
Second-degree relatives diagnosed at any age	2.52	0.99–6.46
Two or more affected first-degree relatives	4.39	2.61–7.39

diagnosed at any age		

Data from Kiciński M, Vangronsveld J, Nawrot TS. An epidemiological reappraisal of the familial aggregation of prostate cancer: a meta-analysis. *PloS One* 6(10):e27130, 2011.

Various research methods have been employed to identify genetic variation associated with prostate cancer. Linkage studies identified possible loci on several chromosomes, but with the exceptions of *BRCA1*, *BRCA2*, and *HOXB13*, most have not been consistently replicated by subsequent studies (Eeles et al., 2014). This suggests that the hereditary etiology of prostate cancer has a significant polygenetic inheritance. With advances in genomic technology utilizing databases of millions of common single-nucleotide polymorphisms (SNPs), genome-wide association studies (GWAS) have further identified candidate loci associated with prostate cancer. **Using this technique, several prostate cancer susceptibility loci, confirmed in more than one study, have been identified on chromosomes 3, 5, 6, 7, 8, 9, 11, 15, 16, 17, 19, and 22** (PDQ Cancer Genetics Editorial Board, 2002)**. Genetic variants identified from GWAS do not pose a clinically significant effect on their own, but the risk is cumulative and increases with increasing number of risk alleles present in an individual.** One approach to this challenge is to combine multiple risk alleles into a predictive model, as risk increases with the number of specific alleles carried. **A polygenic risk score composed of the full complement of risk SNPs has been proposed, and is estimated to account for a 2.9-fold increased risk for prostate cancer among men in the top 10% risk group, and a 5.7-fold risk increase among men in the top 1% risk group, compared with the population average risk** (Al Olama et al., 2014).

To date, however, GWAS findings are estimated to account for only 33% to 50% of heritable prostate cancer risk (Gudmundsson et al., 2012). Ongoing research is continuing to uncover the remaining portion of genetic risk, including the discovery of rarer alleles with higher ORs for risk. **The performance of predictive models based on germline alleles and thus their clinical utility may improve with the incorporation of these rarer variants that confer higher risk.** Several such variants, with a minor allele frequencies approximately 1%, have recently been described for prostate cancer. A recurrent mutation in the coding region of the *HOXB13* gene (i.e., *G84E* pathogenic variant), which maps to an area of interest at 17q21-22 identified by GWAS, was present in 1.34% of cases compared with only 0.28% of controls and was significantly more common in men with early-onset, familial prostate cancer (3.1%) than in those with late-onset, sporadic disease (0.6%) (Ewing et al., 2012;

Witte et al., 2013). This mutation increases overall risk for disease almost 5 times, and more than 8 times in men younger than 55 years of age or with a family history (Witte et al., 2013). Lifetime risk for prostate cancer among *G84E* carriers is estimated between 33% to 60% (MacInnis et al., 2013). Although the exact mechanism with which *HOXB13* contributes to the pathogenesis remains unknown, it has been shown to play a role in prostate cancer development and interacts with the androgen receptor (AR) (PDQ Cancer Genetics Editorial Board, 2002). However, the implications of the *HOXB13 G84E* pathogenic variant for genetic counseling is currently unclear.

Several studies have suggested a familial coaggregation of prostate cancer with breast cancer (Goldgar et al., 1994; Thiessen, 1974; Tulinius et al., 1992), and there is clear evidence that both *BRCA1* and *BRCA2* carriers are at increased risk for prostate cancer, especially early-onset disease. *BRCA1* has been estimated to increase risk by 1.8- to 3.5-fold and *BRCA2* from 4.6- to 8.6-fold in men younger than 65 years of age (reviewed in Castro and Eeeles, 2012). ***BRCA*-associated cancers, especially for *BRCA2*, are also more likely to present with higher-grade, locally advanced, and metastatic disease and have poorer cancer-specific and metastasis-free survival after prostatectomy** (Castro et al., 2015)**. One recent study found that early-stage *BRCA2*-associated prostate cancers are characterized by de novo aberration in genes usually associated with metastatic disease** (Taylor et al., 2017)**.**

Using germline information to predict the risk for developing prostate cancer for individuals or on a population basis has yet to be realized because of low penetrance of relevant alleles in the general population; cost; lack of ability of most alleles (*BRCA* being a notable exception) to predict for disease that is biologically significant; and lack of evidence that targeted prevention strategies or early intervention will have a meaningful impact on outcome (Fig. 148.3). That being said, multigene tests for variants associated with prostate cancer susceptibility are currently available and increasingly being used clinically, and centers are studying the utility of germline testing and counseling in these patients. A recent consensus conference established guidelines for their use (Giri et al., 2018).

FIG. 148.3 Germline influences on susceptibility to prostate cancer. The genetic architecture of prostate cancer illustrates that susceptibility is highly likely to be caused by a mixed model of common and rare genetic variants. (Reproduced with permission from Eeles R, Goh C, Castro E, et al. The genetic epidemiology of prostate cancer and its clinical implications. *Nat Rev Urol* 11[1]:18–31, 2014.)

Inflammation and Infection

Infections cause about 16% of all cancers worldwide (de Martel et al., 2012). **Chronic inflammation leading to cellular hyperproliferation to replace damaged tissue contributes to the development of infection-associated cancers of the colon, esophagus, stomach, bladder, and liver** (Coussens and Werb, 2002; De Marzo et al., 2007)**. Accumulating evidence suggests that a similar process may underlie the development of prostate cancer, and although no specific infectious agent has been identified, inflammation resulting from infection, dietary intake, or other causes likely contributes to development and progression of early-stage disease. Attempts have been made to establish an epidemiologic link between inflammation on prostate biopsy and the subsequent development of prostate cancer, however, these studies are susceptible to detection bias. In one study that circumvents this problem, men initially enrolled in the PCPT who had negative end-of-study biopsies and who were subsequently enrolled in the Selenium and Vitamin E**

Cancer Prevention Trial (SELECT) were monitored for prostate cancer development. The study found that inflammation on negative biopsy was associated with the later development of prostate cancer (Platz et al., 2017)**.**

Inflammatory infiltrates and the histologic lesion called proliferative inflammatory atrophy (PIA) are frequent in clinical prostate specimens (De Marzo et al., 1999). PIA is a spectrum of lesions characterized by epithelial atrophy, low apoptotic index, and an increased proliferative index, usually associated with inflammatory infiltrates (Putzi and De Marzo, 2000). PIA appears to be a regenerative lesion appearing as a consequence of infection or cell trauma resulting from oxidant damage, hypoxia, infection, or autoimmunity, and its hyperproliferative state may lead to cancer. PIA is often found adjacent to high-grade prostatic intraepithelial neoplasia (HGPIN) or early cancer (Putzi and De Marzo, 2000), and there is an identifiable genetic pathway between PIA, HGPIN, and cancer (Nakayama et al., 2003; Nelson et al., 2003; Shah et al., 2001).

Genetic alterations in genes that regulate the inflammatory response and mediate DNA repair, and histologic observations in prostate cancer strongly suggest that compromised cellular defenses against inflammatory oxidants may initiate and/or perpetuate prostatic carcinogenesis (Klein and Silverman, 2008). Although the exact mechanisms remain unclear, one hypothesis is that reactive oxygen species (ROS) and reactive nitrogen species released by immune cells cause direct DNA damage and genetic instability in an environment where epithelial cell proliferations stimulated by immune cells is occurring (Fig. 148.4) (Sfanos et al., 2018). Another potential mechanism relates to the recruitment of epigenetic machinery to sites of DNA damage resulting from the oxidative stress, including DNA methyltransferases, chromatin remodelers, and repressor complexes (O'Hagan et al., 2008, 2011). Recently, in vitro studies of prostate epithelial cells exposed to oxidative stress and AR signaling were found to develop *TMPRSS2-ERG* gene fusions (Mani et al., 2016). Inflammation may also contribute to carcinogenesis through stimulating the development of intermediate cells, which are suspected target cells for prostate carcinogenesis (van Leenders et al., 2003).

FIG. 148.4 Effects of inflammation on early events in prostate cancer. (Reproduced from Sfanos KS, Yegnasubramanian S, Nelson WG, De Marzo AM. The inflammatory microenvironment and microbiome in prostate cancer development. *Nat Rev Urol* 15[1]:11–24, 2018.)

There has been much interest and effort in trying to isolate and identify an infectious agent or agents that cause prostate cancer. **However, recent studies assessing the association between infection and prostate cancer have shown mixed results.** In the Health Professionals Follow-up Study (HPFS) (Sutcliffe et al., 2006), a prospective study of 51,529 American male health professionals 40 to 75 years of age, no association was found between a self-reported history of gonorrhea or syphilis and prostate cancer, although the incidence of sexually transmitted infection (STI) was very low in this population. In addition, no overall correlation between prostate cancer and clinical prostatitis was found. Similarly in this cohort, no associations were observed between *Chlamydia trachomatis*, human papillomavirus (HPV)-16, HPV-18, and HPV-33 antibody seropositivity and prostate cancer (Sutcliffe et al., 2007b). To date, no single microorganism (bacterial, viral, or other) has emerged as the driver of inflammation associated with prostate cancer or as a significant contributor to prostate carcinogenesis. Evidence supports the theory that multiple different microorganism species lead to prostate inflammation. One study that sequenced microbial DNA in prostatectomy samples from men with prostate cancer found DNA from multiple different bacterial species (Sfanos et al., 2008). The authors concluded that microorganisms are present in focal regions of the prostate, perhaps in those associated with foci of acute or chronic inflammation. The discovery of the urinary microbiome, with multiple diverse microorganisms, suggests that prostates are exposed to multiple types of bacteria that elicit prostatic inflammation, contributing to the inflammatory microenvironment associated with prostate cancer. Studies characterizing the microbiota in urine from adult men found common genera, including *Corynebacterium, Streptococcus, Veillonella, Prevotella, Anaerococcus, Propionibacterium, Finegoldia, Staphylococcus, and Lactobacillus* (Dong et al., 2011; Fouts et al., 2012; Nelson et al., 2010). Whether susceptibility to prostatic infection, chronic inflammation, or the development of prostate cancer is determined by the composition of the urinary flora has not yet been determined. **At present, no infectious agent has been proven to cause prostate cancer.**

Molecular Epidemiology

Molecular epidemiologic approaches have identified many biomarkers of exposure measured in blood or tissue and evaluated them in relation to incidence or mortality. These biomarkers capture aspects of diet, environmental exposures, and hormonal and other factors for which concentrations are partly genetically determined. A brief survey of major molecular epidemiologic studies relating to prostate cancer is presented.

Androgens

Androgens influence the development, maturation, and maintenance of the prostate, affecting both proliferation and differentiation of the luminal epithelium. Exposure of the prostate to androgens at key developmental times plays an important role in prostate carcinogenesis. Androgens are also important in the maintenance of established cancers, as supported by clinical experience where the majority of prostate cancers initially respond to androgen deprivation, by the central role of AR biology in castrate-resistant disease, and by results of the PCPT and the Reduction by Dutasteride of Prostate Cancer Events (REDUCE) trial, which demonstrated that inhibition of the conversion of T to the more potent dihydrotestosterone (DHT) by a 5α-reductase inhibitor reduces the incidence of prostate cancer by 25% to 30% (Andriole et al., 2010; Thompson et al., 2003, 2013). Establishing the precise effect of androgens on risk is complicated by the complex biology of the androgen axis: (1) androgen levels are affected by both synthesis and metabolism, which are each controlled by multiple genes; (2) the biologic effects of androgen are exerted at the cellular level by its interaction with the AR; and (3) intraprostatic and serum levels of specific androgens may differ. **Polymorphisms in both synthetic and metabolic genes, including AR** (Balic et al., 2002)**, the type 2 5α-reductase isoenzyme** (Li et al., 2013; Makridakis and Reichardt, 2004), **and genes involved in T biosynthesis** (Chang et al., 2002), **have been reported to affect risk. A meta-analysis of 47 published studies with 13,346 cases and 15,172 controls concluded that men with shorter CAG repeats in the AR were at higher risk for prostate cancer, with an OR of 1.21 (95% CI, 1.10 to 1.34), with the effect most evident in Caucasians and Asians** (Sun and Lee, 2013). Polymorphisms in both the type 1 and type 2 5α-reductase genes have been shown to affect both circulating and intraprostatic androgen levels (Lévesque et al., 2014).

High serum androgens have long been hypothesized to be a risk factor for prostate cancer. However, studies examining this association have been inconsistent, with only some studies finding an association between specific hormones and prostate cancer risk. **A pooled analysis of 18 prospective studies assessing this association using data from 3886 men with prostate cancer and 6438 control subjects** (Endogenous Hormones and Prostate Cancer Collaborative Group, 2008) **failed to detect an association between the risk for prostate cancer and serum concentrations of T, calculated free T, DHT, DHEA, androstenedione, androstanediol glucuronide, estradiol, or calculated free estradiol.** The only positive finding was a modest inverse association between risk and serum concentration of sex-hormone–binding globulin. **The results suggest that one-time measurements of serum sex hormones in adulthood are not a good measure of prostate cancer risk.** No studies have reported on intraprostatic androgen levels as a measure of risk in unaffected men.

Estrogens

Estrogens have both direct and indirect effects on prostatic growth and development and likely play a role in prostate cancer initiation and progression. Traditionally, estrogens have been considered protective against prostate cancer and have been used as a treatment for advanced disease. This treatment effect is primarily through a negative feedback on the hypothalamo-pituitary-gonadal axis, and also through a direct inhibitory effect of estrogens on prostate epithelial cell growth. **However, there is increasing direct evidence**

that estrogens may act as procarcinogens in the prostate. In a seminal study, isolated prostate progenitor cells from normal human prostate that were grown in three-dimensional culture to form prostatospheres expressed estrogen receptor (ER)α, ERβ, and estrogen-responsive G protein–coupled receptor 30 messenger RNA (mRNA) and protein, and grew in response to exogenous estradiol (Hu et al., 2011). When cocultured with rat urogenital sinus mesenchyme and grown in a renal subscapular model, subsequent exposure to T and estradiol resulted in the sequential induction of epithelial hyperplasia, PIN, and locally invasive prostate cancer from the human progenitor cells, providing direct evidence that these cells are estrogen sensitive and that estradiol is a carcinogen for human prostate epithelium. Proposed underlying mechanisms for this effect include epigenetic modifications (especially in utero), genotoxicity, induction of hyperprolactinemia, proinflammatory changes, and prostatic ER-mediated changes (Nelles et al., 2011). In a rat model, a significant increase in prostate cancer incidence was seen when estrogen was given in conjunction with T compared with rats given T alone (90% to 100% vs. 35% to 40%) (Bosland, 2013). The bulk of reported evidence relates to ER-mediated effects (Prins and Korach, 2008). ERα expression, present in stromal and basal cells, is silenced in early prostate cancers, and re-emerges with disease progression. ERα knockout mice have resistance to the development of prostate cancer when given the combination of T and estrogen, suggesting a role for ERα in prostate cancer induction (Ricke et al., 2008). Prostate epithelial ERβ is also thought to play an important role in cancer initiation, with loss of ERβ potentially contributing to disease progression in organ-confined disease (Prins and Korach, 2008). The re-emergence of ERβ expression in metastatic prostate cancer suggests a potential role in progression to castrate-resistant disease.

At a more macro level, age-related prostatic disease parallels increases in serum estrogens, and there is a low incidence of prostate cancer in cultures with diets rich in phytoestrogens (Denis et al., 1999). As for androgens, serum levels of estrogen do not correlate with prostate cancer risk (reviewed in Nelles et al., 2011), though it is clear that that estradiol can be produced from T by intraprostatic aromatase (Ellem et al., 2004), and its potential biologic effects may not be evident from serum levels. **Interestingly, an aromatase knockout mouse model demonstrated a lower risk for prostate cancer compared with wild-type mice after exposure to T and estrogen; the results suggest that intraprostatic estrogen production is important in prostate cancer development** (Ricke et al., 2008). Similar to effects seen for androgen metabolism genes, polymorphisms in two estrogen metabolism genes, *CYP1B1* and *CYP19*, have been observed to increase risk for prostate cancer in a cohort of French men (Cussenot et al., 2007), and polymorphisms in *CYP19A1* and *UGT1A1* were associated with increased risk in the PCPT (Tang et al., 2011).

Insulin-like Growth Factor Axis

Insulin-like growth factors (IGF) are peptide hormones that play an essential role in metabolism and body growth and exert influence on fundamental cellular processes including proliferation, migration, and differentiation. The IGF axis consists of two ligands (IGFI and IGFII), two receptors (type I IGFR-IR and IGF-II/M6P-R), and six binding proteins (numbered IGFBP-1 to -6), the latter of which modulate IGF bioavailability (Biernacka et al., 2012). IGFs may also bind the insulin receptor, and it and the IGF receptors share many downstream targets, making the interaction of these molecules complex.

IGFs promote proliferation and inhibit apoptosis in normal prostate and tumor cells in vitro (Uzoh et al., 2011)**. The IGFBPs can influence prostate growth independent of IGF.** In particular, IGFBP-2 stimulates proliferation, and IGFBP-3 promotes apoptosis and may mediate growth inhibition by 1,25-dihydroxyvitamin D (Chatterjee at al, 2004; Ingermann et al., 2010). IGFBP-3 can be cleaved by PSA, reducing its proapoptotic activity (Koistinen et al., 2002). In cell lines, IGF-1 can bind and activate the AR in the absence of androgen and promote androgen-independent growth (Krueckl et al., 2004).

Results of epidemiologic studies linking the IGF axis to risk have shown mostly null results, although the data suggests a potential effect on cancer progression rather than initiation (reviewed in Uzoh et al., 2011). For example, in the PLCO, there was no association of the IGF axis with risk for developing prostate cancer, but a suggestion that the ratio of IGF-1:IGFBP-3 in obese men was predictive of disease aggressiveness (Weiss et al., 2007).

Leptin

Leptin, a peptide hormone produced by adipocytes, contributes to the control of body weight by appetite suppression and modulating energy utilization (Friedman, 2002). Obese men become leptin resistant and exhibit elevated plasma leptin (Chu et al., 2001). **Epidemiologic studies assessing the association between circulating leptin concentrations with prostate cancer**

have yielded mixed results (Chung and Leibel, 2006). A meta-analysis concluded that a germline variant allele in the *LEP* gene is associated with a 1.2 to 1.3 times increased risk (He and Xu, 2013). **There is evidence that leptin plays a role in the development of advanced disease** (Ribeiro et al., 2006), by growth stimulation of the androgen-independent prostate cancer cell lines DU145 and PC-3 (Deo et al., 2008; Hoda et al., 2012; Somasundar et al., 2004) inducing expression of vascular endothelial growth factor, transforming growth factor β_1, and basic fibroblastic growth factor, and stimulation of cell migration via upregulation of αvβ3 integrin and intracellular signal transduction (Huang et al., 2011). Recent evidence supports another mechanism of prostate cellular migration induced by leptin through its influence on estrogen metabolism and increased expression of ERα and a decrease in ERβ (Habib et al., 2015). A variant allele in the gene for leptin receptor, *LEPR,* was found to be the strongest predictor among five candidate genes for fatal prostate cancer in a Swedish population-based study (Lin et al., 2011).

Vitamin D, Vitamin D Receptor, and Calcium

Vitamin D (1,25 dihydroxyvitamin D_3) is an essential vitamin that is a part of the steroid hormone superfamily. Human sources include both dietary intake and sunlight exposure, which converts inactive to active vitamin D in the skin. **Interest in vitamin D as a determinant of prostate cancer risk comes from epidemiologic observations** (Schwartz, 2013)**: (1) men living in Northern latitudes with less exposure to sunlight-derived ultraviolet exposure have a higher mortality rate from prostate cancer; (2) prostate cancer occurs more frequently in older men, in whom vitamin D deficiency is more common both because of less ultraviolet exposure and age-related declines in the hydroxylases responsible for synthesis of active vitamin D; (3) African-Americans, whose skin melanin blocks ultraviolet radiation and inhibits activation of vitamin D, have the highest worldwide incidence and mortality rates; (4) dietary intake of dairy products rich in calcium, which depresses serum levels of vitamin D, is associated with a higher risk for prostate cancer; and (5) Native Japanese, whose diet is rich in vitamin D derived from fish, have a low incidence of prostate cancer. In addition, prostate cancer cells express vitamin D receptor (VDR), and many studies have demonstrated significant biologic effects of vitamin D including inducing cell cycle arrest and inhibiting invasion, cell migration, metastasis,**

angiogenesis, and inflammation.

Like other steroidal regulators of prostate growth (i.e., androgens and estrogens), normal prostate epithelial cells can synthesize vitamin D, which, in turn, can inhibit their growth (Barreto et al., 2000). The enzyme that converts the prohormone 25-hydroxyvitamin D (25-OHD) to the most active form of 1,25 hydroxyvitamin D (1,25-OHD), is diminished in prostate cancer, leading to a potential loss of autocrine-regulated growth inhibition (Whitlatach et al., 2002). VDR, which binds to 1,25-OHD from serum-derived (diet, sunlight, and paracrine sources) and autocrine sources, is also widely expressed by normal prostate epithelium (Krill et al., 2001). VDR polymorphisms have been associated with prostate cancer risk in some meta-analyses (Yin et al., 2009), but not in others (Shui et al., 2015; Wang et al., 2016). Studies of plasma vitamin D levels and prostate cancer risk are mixed, with most showing no or a weak association (reviewed in Schwartz, 2013). However, there appears to be an association of vitamin D levels and adverse pathology in men undergoing radical prostatectomy (Nyame et al., 2016), as well as risk for lethal prostate cancer, as illustrated by findings in the Health Professional Follow-up Study and the Malmo Diet and Cancer Study (Brändstedt et al., 2016; Shui et al., 2012). However similar associations were not observed in an analysis of the National Cancer Institute Breast and Prostate Cancer Cohort Consortium (Shui et al., 2012).

A meta-analysis of 45 observational studies found null results for dairy, milk, calcium, or vitamin intake and risk for prostate cancer (Huncharek et al., 2008). However, other studies found that the associations between calcium and vitamin D intake and aggressive prostate cancer varied by race, with African-Americans most susceptible to the effects of these micronutrients (Batai et al., 2017; Nelson et al., 2016).

Other Influences

Sexual Activity/Sexually Transmitted Diseases.

Sexual activity has been hypothesized to expose the prostate to infectious agents that may increase the risk for cancer by direct infection with a carcinogenic organism (akin to HPV and cervical cancer) or by initiating an inflammatory response that has known downstream carcinogenic effects. A sexually transmitted etiology for prostate cancer was first proposed in 1950s based on an observed increased prevalence in uncircumcised men (Ravich and

Ravich, 1951). A seminal meta-analysis, published in 2002, suggested an elevated risk for prostate cancer among men with a history of STI (especially for syphilis), increasing frequency of sexual activity, and a higher number of sexual partners (Dennis and Dawson, 2002), however, subsequent case-control and cohort studies have not always confirmed these observations (reviewed in Sutcliffe, 2010). **Prospective studies that have included measurement of serologic markers of STI have generally reported null findings.** For example, in the PLCO, although a borderline increased risk for prostate cancer for a history of any STI was observed, null results were reported for serum levels of antibodies to *Chlamydia trachomatis*, HPV-16 and -18, HSV-2, CMV, and HHV-8 (Huang et al., 2008). A prospective cohort study of more than 68,000 men in California reported that those with a history of prostatitis or longer duration of prostatitis symptoms had an increased risk for prostate cancer compared with men with no history (RR 1.30) or shorter duration of symptoms (Cheng et al., 2010). However, this risk disappeared in those screened for cancer, and a history of STIs was not associated with risk. More recent work has identified two nontraditional infectious agents, the protozoan *Trichomonas vaginalis* and the skin bacterium *Propionibacterium acnes* as potential causes of prostatic infection and inflammation that are associated with increased risk for prostate cancer (Shinohara et al., 2013; Sutcliffe, 2010).

Studies have also suggested a protective association between prostate cancer and frequency of ejaculation, with RR ranging from 0.66 to 0.89 (Giles et al., 2003; Leitzmann et al., 2004). In the Giles study, the protective effect was seen in men who reported more than 5 ejaculations/week in their twenties; the large prospective cohort study by Leitzmann (2004) demonstrated a protective effect for men reporting 21 or more ejaculations/month in their twenties and forties, in the previous year, and as a lifetime average. Another study, examining the association between sexual activity and the risk for prostate cancer diagnosed before 60 years of age, found differing effects at different ages. Frequent overall sexual activity in men in their twenties increased the risk for prostate cancer, but appeared to be protective against the disease in men in their fifties (Dimitropoulou et al., 2009). The biologic basis for this effect is not known.

Vasectomy.

A relationship between vasectomy and prostate cancer risk was initially suggested in a case-control study published in 1988 (Honda et al., 1988) and seemingly confirmed a few years later with the report of a relative risk of 1.6

based on two large cohort studies (Giovannucci et al., 1993a,b). Not all subsequent studies have been confirmatory (reviewed in Köhler et al., 2009), and the positive studies are limited by potential confounders including differences in vasectomy rates between cases and controls and detection bias resulting from a higher likelihood that someone undergoing vasectomy will see a urologist for screening. **A recent systematic review and meta-analysis that took into account risk for bias among 16 cohort studies, 33 case-control studies, and 4 cross-sectional studies found no association between vasectomy and high-grade, advanced-stage, or fatal prostate cancer. There was a weak association between vasectomy and any prostate cancer that was closer to the null with increasingly robust study design** (Bhindi et al., 2017)**. Thus at present, the weight of evidence does not support an increased risk for prostate cancer in men who have undergone vasectomy.**

Smoking.

Cigarette smoking may be a risk factor for prostate cancer because it is a source of cadmium exposure, increases circulating androgen levels, and causes significant cellular oxidative stress. **Meta-analyses have not consistently found an association between smoking and the incidence of prostate cancer, but have demonstrated increased prostate cancer mortality among current smokers** (Huncharek et al., 2010; Ordonez-Mena et al., 2016)**. Some studies have suggested an association with higher grade and more advanced stage at diagnosis** (Byrne et al., 2010; Tang et al., 2017)**, and there is some evidence that current smokers are at higher risk for biochemical recurrence and metastasis than nonsmokers across all treatment modalities, even when intensity of screening is accounted for** (Kenfield et al., 2011; Moreira et al., 2014).

Diet.

Descriptive epidemiologic studies of migrants, geographic variations, and temporal studies suggest that dietary factors may contribute to prostate cancer development (Bostwick et al., 2004). The incidence of latent prostate cancers is similar around the world, but the incidence of clinically manifest cancers differs, with Asians having the lowest rates of clinical disease (Center et al., 2012). **Thus, the most convincing evidence for the role of the diet and other environmental factors in modulating prostate cancer risk comes from migration studies showing an increased incidence of prostate cancer in first-**

generation immigrants to the United States from Japan and China (Muir et al., 1991; Shimizu et al., 1991). These observations suggest that diet may play a role in tumor progression, allowing latent cancers to become clinically evident. A strong positive correlation exists between prostate cancer incidence and the corresponding rates of several other diet-related cancers, including breast and colon (Bostwick et al., 2004). However, the prospective epidemiologic evidence linking diet to prostate cancer risk is largely inconsistent, which was verified in a recent umbrella review in which only 21% of the examined meta-analyses gave nominally statistically significant findings (Markozannes et al., 2016). Most meta-analyses yield effect sizes between 0.95 and 1.05, raising the question of whether the observed risk estimates represent true magnitude of association, or are caused by chance or bias.

Epidemiologic studies have also suggested a moderate to strong association between total and specific fats and the risk for developing prostate cancer (Chan et al., 2005). **However, results from large prospective studies showed no association between dietary fat intake and prostate cancer risk** (Crowe et al., 2008; Park et al., 2007; Wallström et al., 2007). A meta-analysis of observational studies demonstrated only a weak association between higher intake of total fat and risk for prostate cancer (RR 1.2) (Dennis et al., 2004). Observations on the association of dietary fat and risk may have alternative explanations. Diets high in meat that are sources of fat are also usually low in vegetables that contain nutrients that may protect against prostate cancer. Meats and dairy products also contain other constituents, such as zinc and calcium, that may affect prostate cancer risk. Furthermore, some have implicated the cooking process in the association between red meat intake and the risk for prostate cancer. Cooking these meats at high temperatures creates both heterocyclic aromatic amine and polycyclic aromatic hydrocarbon carcinogens (Knize et al., 1997; Lijinsky and Shubik, 1964). The best studied of these carcinogens for prostate cancer is 2-amino-1-methyl-6-phenylimidazopyridine (PhIP). In rat models, PhIP ingestion causes PIA and prostate cancer (Shirai et al., 1997). It is thought to cause prostate epithelial cell damage and elicit inflammatory responses leading to DNA damage/mutations (Nakai et al., 2007). Other mechanisms by which diet is thought to contribute to prostate carcinogenesis includes DNA and histone methylation as well as histone acetylation (Labbe et al., 2015).

The nutritional complexity of the typical Western diet, the association of healthier dietary habits with healthier lifestyle choices (physical activity and smoking avoidance), and the potential interaction of specific nutrients with

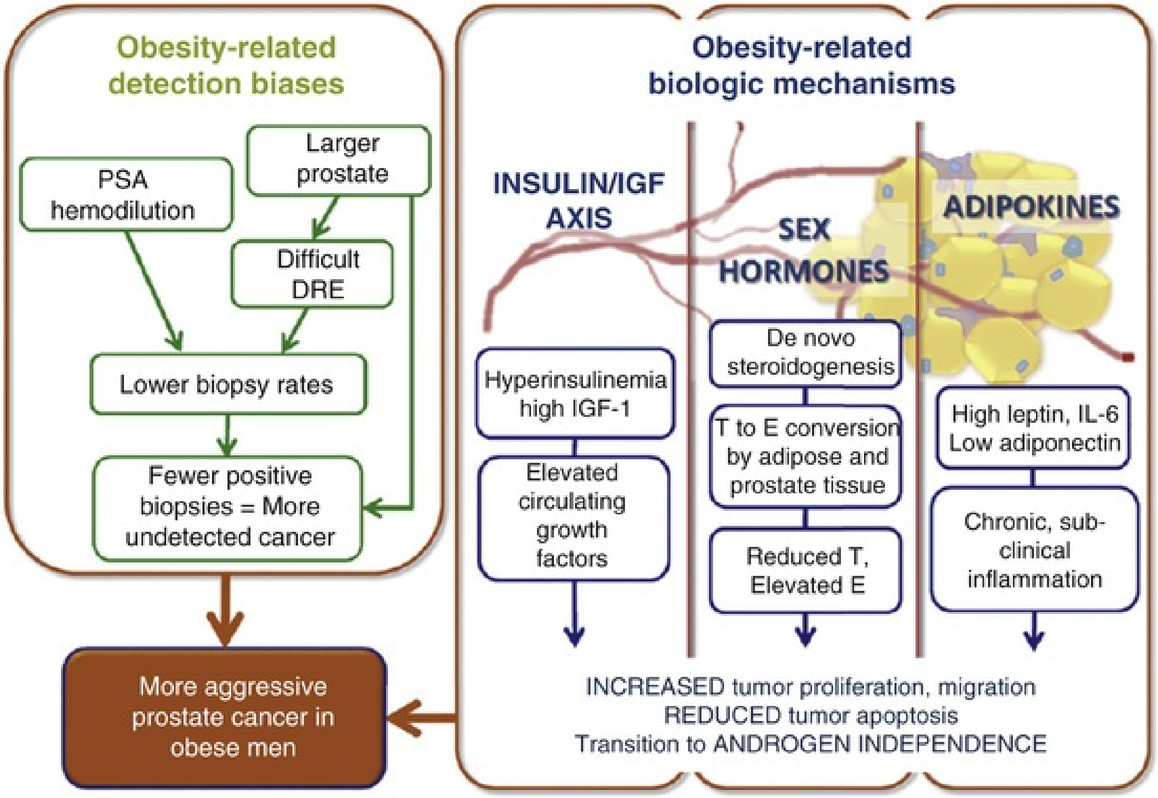
genetic variability among individuals are significant limitations to understanding how diet influences risk. Masko et al. (2013) summarized the state of preclinical and clinical evidence that specific dietary components may exert on prostate cancer risk and progression. Recent revelations about the role of intratumoral androgen in driving castrate-resistant prostate cancer have increased focus on cholesterol as a risk factor (Sharifi, 2013). Intracellular cholesterol may be carcinogenic by being a proximate steroidal precursor to both T and DHT, and by enhancing *Akt* signaling (Lee et al., 2012). Recent molecular work has demonstrated that ABCA1, the major cellular cholesterol efflux transporter, is preferentially downregulated by promoter hypermethylation in intermediate- to high-grade prostate cancers and that its expression levels are inversely correlated with Gleason grade (Lee et al., 2012). Further, lethal prostate cancers have been shown to rely on de novo cholesterol synthesis, rather than transcellular uptake (Stopsack et al., 2017). **Coupled with epidemiologic evidence that lower levels of serum cholesterol and use of cholesterol-lowering agents (statins) reduce the risk for aggressive and advanced-stage disease, loss of cholesterol homeostasis may be a contributor to prostate cancer risk and progression** (Platz et al., 2006, 2009).

Obesity.

Obesity as measured by BMI has been suggested to be a risk factor for prostate cancer because of its common occurrence in middle-aged men and clear links to colon and breast cancer risk (Giovannucci, 1995; Madigan et al., 1998). White fat in mammals serves not only as an important energy reservoir, but also as an endocrine organ, with secretion of cytokines and agents with cytokine-like activity (TNFα, IL-1β, IL-6, IL-8, IL-10, TGFβ) and their soluble receptors (Trayhurn and Wood, 2004). Treatment of obesity through reduction in fat intake and increased exercise has been shown to reduce oxidative stress, suggesting that lifestyle modification could be important in reducing the risk for prostate cancer (Roberts et al., 2002).

Current evidence has failed to show a clear link between obesity and overall prostate cancer incidence (Yang et al., 2016)**. A meta-analysis of 27 cohorts found a modest, nonsignificant 1.03 (95% CI, 1.00 to 1.07) per 5 kg/m^2 increase in BMI relative risk for prostate cancer** (Renehan et al., 2008). However, several studies have suggested an association between obesity and an increased risk for high-grade disease and prostate cancer death (De Nunzio et al., 2013; Perez-Cornago et al., 2017). The association between obesity and high-grade disease was also observed in the PCPT, a study in which all men underwent biopsy, making it unlikely that detection bias is solely responsible for this finding (Gong et al., 2006). Potential explanations for the latter observation include the association of obesity with higher serum estradiol, insulin, free IGF-1, and leptin levels, and lower free T and adiponectin levels, which have also been associated with more aggressive prostate cancer (Buschemeyer and Freedland, 2007). Moreover, studies have found genes involved in chromatin regulation, RNA processing, and cellular disassembly enriched in tumor tissue of overweight and obese prostate cancer patients when compared with healthy-weight patients, suggesting that obesity may promote tumor progression in part by influencing the epigenetic state of prostate cancer (Ebot et al., 2017).

Obesity has also been shown to be associated with higher rates of biochemical failure after surgery or external-beam radiotherapy and a 15% to 20% increase per 5 kg/m^2 increase in BMI in prostate specific-cancer mortality (Masko et al., 2013). These observations likely reflect higher-grade and more locally advanced disease at presentation, technical challenges in surgery and radiotherapy in obese men, and more aggressive biology driven by adipocyte-derived biologic factors. This complex interplay and the specific molecular mechanisms that may underlie the biologic effects of obesity are illustrated in Fig. 148.5.



Obesity-related detection biases
PSA hemodilution
Larger prostate
Difficult DRE
Lower biopsy rates
Fewer positive biopsies = More undetected cancer
More aggressive prostate cancer in obese men
Obesity-related biologic mechanisms
INSULIN/IGF AXIS
SEX HORMONES
ADIPOKINES
Hyperinsulinemia high IGF-1
Elevated circulating growth factors
De novo steroidogenesis
T to E conversion by adipose and prostate tissue
Reduced T, Elevated E
High leptin, IL-6 Low adiponectin
Chronic, sub-clinical inflammation
INCREASED tumor proliferation, migration
REDUCED tumor apoptosis
Transition to ANDROGEN INDEPENDENCE

FIG. 148.5 The complex interplay between detection bias and biology in obese men. (Reproduced with permission from Allott EH, Masko EM, Freedland SJ. Obesity and prostate cancer: weighing the evidence. *Eur Urol* 63[5]:800–809, 2013.)

Alcohol Consumption.

Alcohol consumption and risk for prostate cancer is of interest because of its association with other cancers, its effect on estrogen and T, and the high content of polyphenolic compounds with antioxidant activity in red wine. Epidemiologic studies including both case-control and cohort designs have reported mixed results, with some suggesting increased risk, some null, and some suggesting a protective effect of alcohol use (reviewed in McGregor et al., 2013.). A recent meta-analysis found a significant dose-response relationship between level of alcohol intake and risk for prostate cancer, with studies free from misclassification errors producing the highest risk estimates for drinkers versus abstainers in adjusted models (RR 1.22, $P < 0.05$) (Zhao et al., 2016).

Etiology and Molecular Genetics

Prostate cancer exists in two forms: a histologic only or clinically occult form, which can be identified in approximately 30% of men older than 50 years of age and 60% to 70% of men older than 80 years of age, and a clinically evident form, which affects approximately 1 in 6 US men. Latent prostate cancer is believed to have a similar prevalence worldwide and among all ethnicities, whereas the incidence of clinical prostate cancer varies dramatically among and within different countries. For this reason, an understanding of prostate cancer etiology must encompass the steps leading to both the *initiation* of histologic cancer and *progression* to clinically evident disease. The exact molecular relationship between latent and clinical cancers is not known, and it is likely that the progression from the former to the latter is a biologic continuum with overlap in the associated molecular events. **Recent molecular evidence suggests that some low- and high-grade cancers share a common origin, where the tumors share a common precursor and subsequently undergo branched evolution with the accumulation of additional genomic alterations in high-grade disease; further, there is clear evidence that some low-grade (Gleason pattern 3) tumors can appear histologically indolent while containing molecular features of high-grade disease** (Sowalsky et al., 2017). Gene fusions, mutations, downregulation by promoter methylation, changes in gene expression, and protein modification have all been implicated in progression of prostate cancer.

The Influence of Androgens

As discussed earlier, androgens play an important role in prostate carcinogenesis. **The primary androgen of the prostate is DHT, irreversibly catalyzed from T by 5α-reductase.** DHT binds to intracytoplasmic AR with much greater affinity than T, dissociates more slowly than T, enhances translocation of the steroid-receptor complex into the nucleus, upregulates AR synthesis and reduces AR turnover, and activates androgen-responsive genes (Steers, 2001; Swerdloff et al., 2017). Type 1 5α-reductase is expressed primarily in the skin and liver and to lesser extent in prostate, and the type-2 enzyme is expressed predominantly in prostate epithelium and other genital tissues (Andriole et al., 2004a).

Functional type 2 5α-reductase is a prerequisite for normal development

of the prostate and external genitalia in males, and insufficient exposure of the prostate to DHT appears to protect against the development of prostate cancer. Males with inherited 5α-reductase deficiency have miniscule prostatic tissue, and biopsies demonstrate stroma but no epithelium (Zhu and Imperato-McGinley, 2009). **In addition to the lack of enzyme activity, a lack of T may also protect against the development of prostate cancer, as evidenced by the atrophic prostates seen in men after surgical castration** (Wilson and Roehrborn, 1999)**. Nonetheless, there is evidence that even hypogonadal adults can develop prostate cancer** (Morgentaler and Rhoden, 2006) **and that their cancers may be driven by growth pathways that are independent of androgens** (although they may still act through the AR, which is known to exhibit ligand promiscuity).

The preponderance of currently available data suggest that there is no evidence that circulating levels of androgens, including DHT, affect prostate cancer risk because of local regulatory mechanisms that tightly control intracellular androgen homeostasis (Swerdloff et al., 2017). In the placebo arm of REDUCE, there was no association of serum T or DHT levels with risk for prostate cancer or Gleason grade (Muller et al., 2012). Cancer detection was similar among men with low compared with normal baseline T levels, and higher T levels at baseline were associated with higher prostate cancer detection only if men had low baseline T (<10 nmol/L) (OR 1.23; 95% CI, 1.06 to 1.43; $P = 0.006$). For men with normal baseline T (≥10 nmol/L), higher T levels at baseline were unrelated to prostate cancer risk (Fig. 148.6A). A placebo-controlled trial of daily DHT gel supplementation given over 24 months in 114 healthy, eugonadal men older than 50 years of age demonstrated only minor and clinically insignificant changes to serum PSA and prostate volume; there were no cases of prostate cancer diagnosed in either group (Idan et al., 2010). A longitudinal, observational community-based cohort study of more than 3600 men reported no association of circuiting T or DHT levels and prostate cancer risk over a 9-year observation period (Chan et al., 2017). A large case-control study from Sweden that included all newly diagnosed prostate cancer cases between 2009 and 2012 found that use of T replacement therapy had no effect on the risk for being diagnosed with prostate cancer (Loeb et al., 2017). In another double-blind, randomized, placebo-controlled study, exogenous DHT administration had no impact on PSA or intraprostatic androgen levels, and no effect on expression of androgen-regulated genes measured on tissue biopsy (Page et al., 2011). **In summary, these studies suggest that intraprostatic**

levels of androgen are determined locally within the prostate, more likely affected by genetic and metabolic factors than serum concentrations.

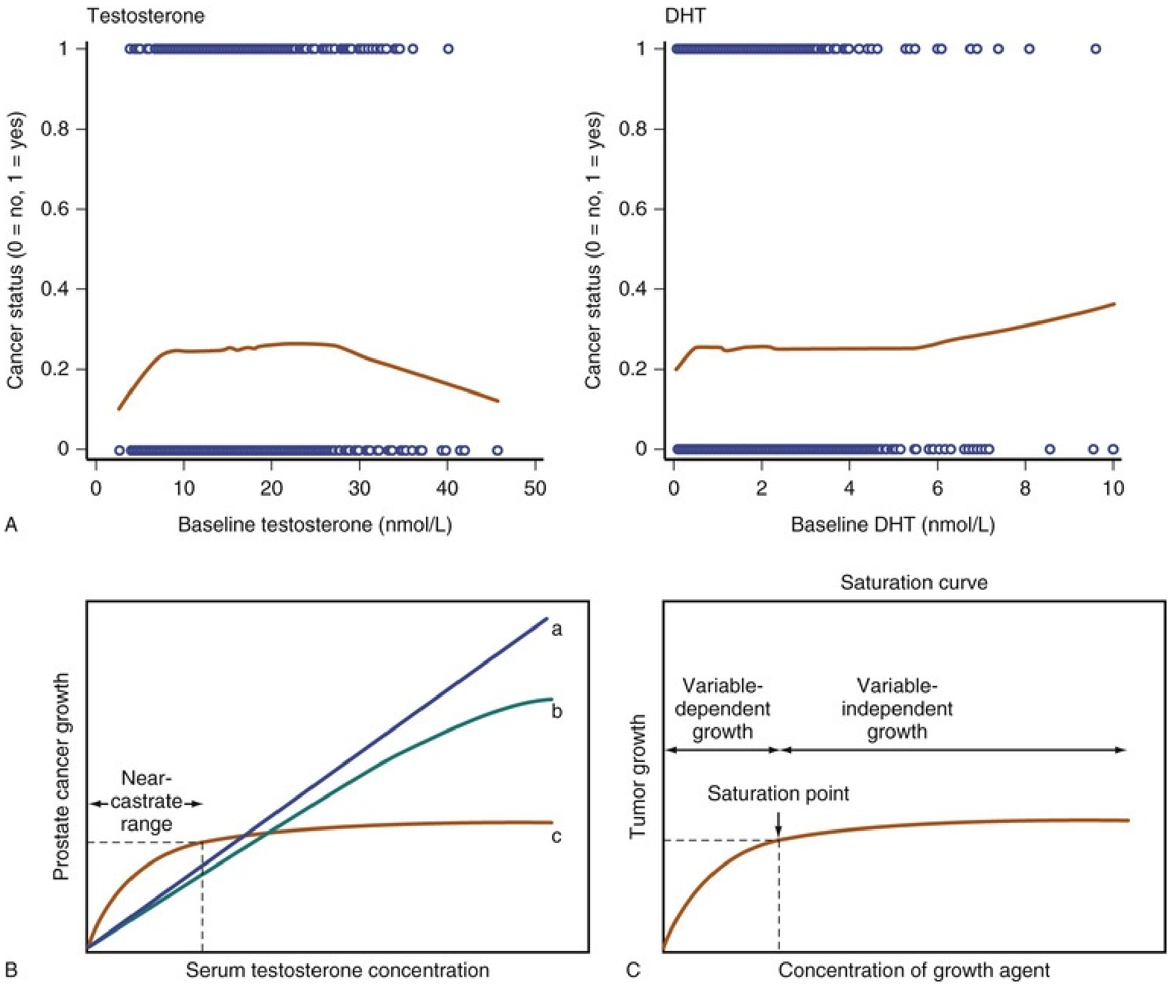


FIG. 148.6 Testosterone and prostate cancer risk in the REDUCE trial. (A) Locally weighted scatterplot smoothing of serum levels of testosterone and dihydrotestosterone *(DHT)* at baseline and final cancer status after considering all biopsies during 4 years of the REDUCE trial. The overlapping circles on the top and bottom of the chart represent each individual case. The left portion of the curve for testosterone mimics that proposed in the saturation model for the effect of androgen on prostate cancer risk (see text). (B) The saturation hypothesis of testosterone and prostate cancer risk. *(a)* The traditional model of testosterone *(t)*-dependent prostate cancer *(pca)* growth suggested that greater serum t concentrations would lead to some degree of greater pca growth *(curves a, b)*. The saturation model *(curve c)* describes a steep t-dependent curve at t concentrations at or below the near-castrate range, with a plateau representing little or no further growth above this concentration. *(b)* the relationship between t and pca appears to follow a saturation curve, present in many biologic systems, in which growth corresponds with

concentration of a key nutrient until a concentration is reached in which an excess of the nutrient is achieved. This type of curve is seen with hormones acting via binding to specific receptors, which have a finite number of binding sites. Once full binding is achieved (saturation) (C), further increases in concentration of the hormone (or other nutrient) produce no further growth. (A, Reproduced with permission from Muller RL, Gerber L, Moreira DM, et al. Serum testosterone and dihydrotestosterone and prostate cancer risk in the placebo arm of the Reduction by Dutasteride of Prostate Cancer Events trial. *Eur Urol* 62[5]:757–764, 2012. B, C, Reproduced with permission from Morgentaler A, Traish AM. Shifting the paradigm of testosterone and prostate cancer: the saturation model and the limits of androgen-dependent growth. *Eur Urol* 55[2]:310–320, 2009.)

These observations also suggest a saturation point for T exposure as a risk factor for prostate cancer, such that further increases in T have no effect on risk. The saturation model hypothesis states that changes in serum or tissue T concentrations below the point of maximal androgen-AR binding will elicit substantial changes in prostate epithelial and cancer growth, but that once maximal binding is reached the presence of additional androgen produces little further effect (Morgantaler and Traish, 2009) (see Fig. 148.6B). This model is supported by animal studies showing that intraprostatic androgen levels and prostate mass in castrated rats are extremely sensitive to serum T around near-castrate levels, but plateau above this level (Wright et al., 1999), and similar findings in intact rats showing that normal prostate growth plateaus with increasing doses of exogenous T (Banerjee et al., 1994), and by numerous clinical observations in humans (reviewed by Morgantaler and Traish, 2009).

In summary, exposure of the prostate to androgens before or at puberty seems to be prerequisite for later development of prostate cancer, but beyond a certain level of exposure in adulthood the risk is not linear as measured by serum androgen levels.

Stem Cells

Stem cells are required for the maintenance of high cell turnover tissues, where cells continually need to be replaced, and, like most epithelial organs, the prostate contains stem cells capable of multilineage differentiation. **The existence of prostatic stem cells was initially suggested by studies in mice demonstrating the ability of prostate epithelium to regress and regenerate with repeated cycles of castration and androgen replacement** (Bui and Reiter, 1998,1999; Isaacs and Coffey, 1989; Tsujimura et al., 2002)**. The ability of**

these cells to resist androgen deprivation suggest they may be the source of castration-resistant disease. Supportive evidence includes (1) organogenesis experiments demonstrating multipotent basal progenitors that generate basal, luminal, and neuroendocrine progeny, and unipotent luminal progenitors that only generate luminal progeny; (2) the existence of bipotential basal progenitors that undergo asymmetric cell divisions to generate luminal and basal daughter cells during regeneration; and (3) stem-cell–enriched cell populations that can produce three-dimensional structures with basal cells and fully differentiated luminal cells in nude mice (Shibata and Shen, 2015). Several molecular markers (including *Sca1*, *Trop2*, and *DLK1*) are now recognized to reliably identify stem cells and have facilitated their study.

The epithelial cell layer of the prostate, from which adenocarcinomas arise, contains four distinct cell types: basal, secretory luminal, neuroendocrine (NE), and transit-amplifying (TA) cells that have distinct morphology and molecular phenotypes (Prajapati et al., 2013)**. Various genetic events in these cells can result in tumor formation from any of these cell types** (Maitland and Collins, 2008).

Stem cells compose about 1% of the basal cell population, based on specific marker expression and growth characteristics (Collins et al., 2001). In a set of remarkable experiments, Moad et al. (2017) demonstrated that **multipotent basal stem cells reside in a protected niche adjacent to the urethra and populate the epithelium along the entire length of the glandular ducts by means of a cohesive cell migration stream, reaching distally to glandular acini (Fig. 148.7). The data suggest that adult prostatic epithelium is maintained by these stem cells located in the most proximal region of the main ducts, giving rise to bipotent basal progenitors that produce luminal cells only later in the stream, where the microenvironment induces luminal differentiation.** The authors also speculated that **the arrangement of prostate epithelium into discrete long-ranging flows feeding distal ducts in a monoclonal fashion could account for field cancerization and give rise to multifocal tumors sharing clonality.** Interestingly, there is evidence that stem cells contain TRMPSS2:ERG fusions that are thought be one of the earliest events in prostate cancer initiation (Polson et al., 2013). Stem cell biology makes them attractive targets for both prevention and therapy.

Somatic Genetic Changes Associated With Tumor Initiation and Progression

Substantial evidence exists that prostate cancer arises and progresses by genetic alterations that activate oncogenes and inactivate tumor suppressors. These changes result most commonly from epigenetic and structural genomic changes, including gene fusions, mutations, somatic copy number alterations, and chromosomal rearrangements. Unlike many metabolic diseases, the incidence of point and missense mutations resulting in altered proteins are rare in prostate cancer, estimated to occur in only about 1% of primary tumors (Taylor et al., 2010). **A plethora of reports using next-generation sequencing, microarray data, and functional studies has led to an emerging comprehensive understanding of the temporal genomic events that occur in prostate cancer development and progression to the lethal phenotype of metastatic castrate-resistant disease** (Barbieri and Tomlins, 2014; Barbieri et al., 2012) (Fig. 148.8). A comprehensive analysis of primary tumors by The Cancer Genome Atlas (TCGA) has yielded additional insight into the molecular taxonomy of early-stage disease (Cancer Genome Atlas Research Network, 2015).

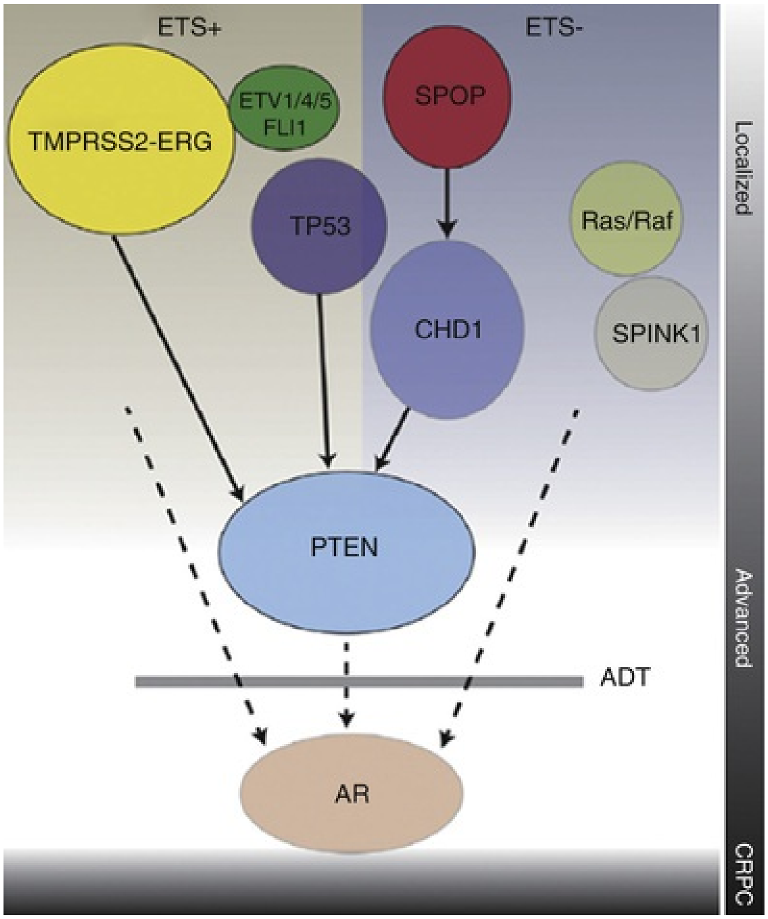

FIG. 148.8 Molecular classification of prostate cancer. Genomic lesions in the time line of prostate cancer. Genes with common genomic lesions (including mutation, rearrangement, or copy number alteration) are shown. *Solid arrows* designate a temporal relationship between events; presumptive “early” lesions are at the top, with “later” lesions below. The Cancer Genome Atlas and Its Findings

The TCGA is the most comprehensive study of early-stage prostate cancer published to date. In this study, 333 tumors were subjected to whole-exome sequencing for detecting somatic mutations, array-based methods for profiling somatic copy-number alterations and DNA methylation, and messenger RNA (mRNA) sequencing. In addition, a subset of tumors underwent microRNA (miRNA) sequencing and reverse-phase protein array (RPPA), and a small number of paired normal and tumor samples were subjected to whole-genome sequencing. **The results allowed molecular classification of 74% of the tumors studied into seven families based on distinct molecular features: gene fusions involving (1) *ERG*, (2) *ETV1*, (3) *ETV4*, or (4) *FLI1*, or mutations in (5) *SPOP*, (6) *FOXA1*, or (7) *IDH1* (Fig. 148.9). The results confirmed prior studies identifying the most frequent genomic alterations in prostate cancer as fusions of androgen-regulated promoters with ERG and other ETS-family transcription factors, accounting for 53% of the cases. In addition to these common gene fusions, the study confirmed a preponderance of *PTEN* deletions in *ERG* fusion–positive cases** (Taylor et al., 2010) **and that tumors with *SPOP* mutations (accounting for about 10% of cases) are mutually exclusive of tumors defined by *ETS* rearrangements.** In this study, 26% of the tumors could not be classified into one of these seven families. New observations from TCGA included (1) identification of a subset of cases defined by *SPOP*-mutant/*CHD1*-deletions with marked DNA methylation, homogeneous gene expression patterns, and overexpression of *SPINK1*; (2) similar mRNA expression levels, copy-number alterations, and methylation profiles in tumors defined by *SPOP* or *FOXA1* mutations; and (3) a new and distinct subtype defined by mutations in *IDH1*. **Another recently reported study of 1577 cases obtained from radical prostatectomy specimens using a genome-wide expression array confirmed that ERG and ETS-family gene fusions define about one-half of primary prostate cancers, with another 8% defined by *SPOP* mutation** (Tomlins et al., 2015). In this study, the proportions of each molecular subtype were similar across eight independent prostatectomy cohorts from the United States and Europe, suggesting that these molecular subtypes are universal. *ERG*-positive tumors were more common in European Americans and associated with lower Gleason scores and pretreatment PSAs. **The molecular subtypes were not predictive of biochemical recurrence, metastasis, or death caused by prostate cancer after prostatectomy, suggesting that the molecular events that define these families are more important for tumor initiation and local growth rather than progression.**

FIG. 148.9 The molecular taxonomy of prostate cancer as defined by The Tissue Cancer Genome Atlas *(TCGA).* Prostate cancer can be classified into those with rearrangements in ETS family transcription factors (e.g., ERG, ETV1, ETV4, and FLI1) and those negative for ETS factors. ETS-negative PCas show recurrent mutations in *SPOP, FOXA1,* and *IDH1.* Alterations in PI3K and p53 signaling are common in ETS-positive cancers, whereas deletions of CHD1 and overexpression of SPINK1 are specific to ETS-negative cancers. *CHD1,* Chromodomain Helicase DNA Binding Protein 1; *FLI1,* Friend Leukemia Virus Integration 1; *FOXA1,* forkhead box A1; *IDH1,* isocitrate dehydrogenase-1; *PCa,* prostate cancer; *PI3K,* phosphatidylinositide 3-kinase; *PTEN,* Phosphatase and Tensin Homolog. Tumors Defined by Gene Fusions

Gene fusions resulting from chromosomal translocations are the most common genetic alteration in human cancers (Futreal et al., 2001) **Recurrent genomic rearrangements in prostate cancer result in the fusion of the 5′ untranslated end of *TMPRSS2* (an androgen-responsive, prostate-specific, transmembrane serine protease gene) to members of the *ETS* family of oncogenic transcription factors** (Tomlins et al., 2005)**. Other important gene fusions involving the *RAF1* kinase family and *SPINK1* have been described, highlighting the fundamental importance of this genetic mechanism in the genesis of prostate cancers** (Rubin et al., 2011) **(Fig. 148.6B).**

ETS Family Gene Fusions

The most common fusion identified in localized prostate cancer involves *TMPRSS2* or other promoters (*SLC45A3* and *NDRG*) fused to *ERG* (ETS-related gene) in 50% to 60% of patients (Cancer Genome Atlas Research Network, 2015; Kumar-Sinha et al., 2008; Rubin et al., 2011). While TMPRSS2-ERG fusions account for 90% of gene fusions seen in prostate cancer, fusions involving other members of the *ETS* family (*ETV1*, ETV4, and *FLI1*) also occur. Both *TMPRSS2* and *SLC45A3* are androgen responsive such that fusion of either of these genes to a growth-promoting gene of the normally androgen-indifferent *ETS* family brings a powerful signal for cellular growth under androgen control. **These fusions are not observed in benign prostate tissue, but are present in prostate stem cells, HGPIN, and early-stage, low-grade prostate cancer, suggesting they are an early and seminal event in prostate tumorigenesis** (Polson et al., 2013; Rubin et al., 2011). Recent data from animal models suggest that defects in the *PTEN/PI3K/Akt* pathway in the presence of *TRMPSS2:ERG* fusions drive early tumor progression, the former stimulating proliferation and the latter cell migration that together may result in a more aggressive phenotype (Carver et al., 2009). **However, there are mixed data on whether the presence of *TMPRSS2:ERG* fusions affect prognosis** (reviewed in Rubin et al., 2011); ERG rearrangement has been observed to be associated with a higher risk for death caused by prostate cancer in two cohorts of men managed by watchful waiting after tumor detection on TURP (Attard et al., 2008; Demichelis et al., 2007), but, as noted earlier, a large study of radical prostatectomy specimens using whole-genome expression analysis found no prognostic value for any molecular subtype (Tomlins et al., 2015). One reason for the discrepancy between studies may relate to epigenetic phenomena. TCGA noted distinct methylation patterns in *ERG*-positive tumors: about two-thirds of all *ETS* fusion–positive tumors had only moderate DNA methylation, and the remaining one-third was characterized by hypermethylation that was almost exclusively associated with *ERG* fusions and distinct from the methylation patterns of *ETV1*-positive and *ETV4*-positive tumors. Furthermore, *ETS*-positive tumors are enriched for *PTEN* deletions, *TP53* alterations, *PI3K* pathway alterations, and specific amplifications in chromosome 3p. The molecular diversity within the *ETS*-positive molecular subset suggests the existence of multiple subfamilies that at present confounds the use of this classification to predict clinical outcomes (Kaffenberger and Barbieri, 2016).

However, **the high specificity of *TPMRSS2:ERG* fusions for cancer makes it an attractive target for other clinical uses.** Fusion transcripts can be detected in the urine, and clinical evidence suggests that when combined with an assay for PCA3, detection of ETS fusions can improve the detection of cancer in screened populations over PSA alone (Tomlins et al., 2011). Some data suggest that quantification of *TPMRSS2:ERG* fusion in urine can predict both tumor volume and tumor aggressiveness, perhaps making it useful for selecting appropriate candidates for active surveillance (Lin et al., 2013). It has been observed that not all tumor foci within a prostate harbor *ETS* fusions, so that a positive urine for *TRMPSS2:ERG* fusion in the face of a negative biopsy would suggest that cancer was missed because of a sampling error, and that additional evaluation with MRI or repeat biopsy is indicated. The presence of gene fusions that occur only in cancer also makes them targets for novel therapies.

Other Gene Fusions

As noted, **prostate cancers also are rarely observed to contain fusions involving *SPINK1* and *RAF* kinases.** *SPINK1* fusions occur in about 10% to 15% of cancers, exclusively in ETS fusion–negative tumors, and in cell lines seem to drive tumor invasion (Tomlins et al., 2008). Fusions involving *RAF* kinases are even rarer and also define another ETS fusion–negative phenotype that is associated with aggressive cancers (Palanisamy et al., 2010). **Both examples likely represent alternative growth pathways for ETS fusion–negative tumors and may represent distinct phenotypes (see Figs. 148.8 and 148.9).**

Tumors Defined by Mutations *(SPOP, FOXA1, IDH1)*

Tumors with mutations in *SPOP* (Speckle-type POZ protein, which mediates ubiquitination leading to the degradation of target proteins) occur in about 10% of primary prostate cancers and define a distinct subclass that lacks *ETS* family gene fusions (Cancer Genome Atlas Research Network, 2015). SPOP mutations have been identified in HGPIN adjacent to adenocarcinoma, suggesting they occur early in tumorigenesis (Jung et al., 2016). **Functional analysis indicates that intact *SPOP* helps mediate DNA double-strand break repair, and consequently mutations in this gene lead to genomic instability, promoting tumor growth** (Boysen et al., 2015) **(Fig. 148.10).** In vitro data show that *SPOP*-mutant tumors may be more sensitive to

DNA-damaging therapeutic agents (such as PARP inhibitors), suggesting that a *SPOP* mutation may be a biomarker for predicting response to these agents. *SPOP*-mutant tumors are also characterized by deletions of *CHD1* (which codes for a chromatin-remodeling enzyme) and frequently by overexpression of *SPINK1* (Serine peptidase inhibitor, Kazal type 1). **Tumors overexpressing *SPINK1* are associated with higher Gleason scores and occur more frequently in African-Americans** (Tomlins et al., 2015).

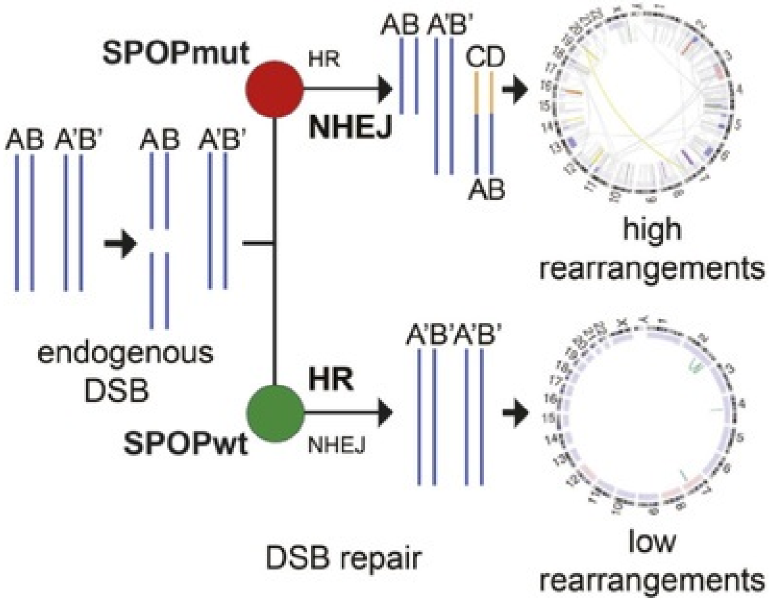

FIG. 148.10 Proposed model of the effects of *SPOP* mutation on genome instability. In prostate epithelial cells, wild-type *SPOP* promotes error-free homologous recombination *(HR)* and maintains genome stability. *SPOP* mutation impairs HR repair and promotes error prone nonhomologous end joining *(NHEJ)* leading to increased genomic instability. (Reproduced with permission from Boysen G, Barbieri CE, Prandi D, et al. SPOP mutation leads to genomic instability in prostate cancer. *Elife* 4:e09207, 2015.)

Tumors with mutations in *FOXA1* (a transcription factor of the AR) occur in about 3% of primary prostate cancers, and as noted earlier, share many molecular features with *SPOP*-mutant tumors, including mRNA, SCNAs, and methylation profiles. *SPOP*-mutant and *FOXA1*-mutant tumors have the highest levels of AR transcriptional activity seen in TCGA. Paradoxically, *FOXA1* stimulates cell proliferation in an AR-dependent manner, but also serves as a tumor suppressor independent of AR (Jin et al., 2013).

A small number of primary prostate cancers (about 1%) are characterized by mutations in *IDH1* (isocitrate dehydrogenase-1), also seen in gliomas and acute myeloid leukemia, albeit with mutations distinct from those seen in nonprostate cancers. **Mutations in *IDH1* result in pan-genomic hypermethylation. IDH1-associated tumors are associated with early age of onset,** and few copy number or other genomic alterations.

Epigenetic Changes

Epigenetic events affect gene expression without altering the actual sequence of DNA. Known mechanisms include DNA hypermethylation and hypomethylation, chromatin remodeling, and microRNA (miRNA) and long-noncoding RNA (lncRNA) regulation, all of which are important in prostate cancer.

DNA hypermethylation generally causes gene silencing and is the most well-characterized epigenetic alteration in prostate cancer, affecting more than 50 genes across a diverse number of basic cellular processes including hormone response (*ERαA*, *ERβ*, and *RARβ)*, signal transduction (*EDNRB* and *SFRP1*), cell cycle control (*CyclinD2* and *14-3-3σ*), DNA repair (*GSTpi*, *GPX3*, and *GSTM1*), inflammatory response genes (*PTGS/COX2*), tumor suppressor genes (*APC*, *RASSF1α*, *DKK3*, *p16INK4α*, *E-cadherin*, and *p57WAF1*), tumor invasiveness (*CD44*), and apoptosis (Li et al., 2005; Jerónimo et al., 2011). DNA hypomethylation, which usually affects areas of the genome distinct from hypermethylated regions, causes activation of oncogenes and leads to genetic instability, and has been reported for genes associated with tumor progression (*CAGE*, *HPSE*, and *PLAU*) (Li et al., 2005). **Promoter methylation of some genes is influenced by diet and age, and is frequently seen in HGPIN and morphologically normal prostate tissue, suggesting that these events are drivers early in the development of prostate cancer and suggest the outgrowth of tumor clones originating from clonal benign and PIN tissue** (Brocks et al., 2014; Massie et al., 2017). Both hypomethylation and hypermethylation define a field cancerization effect in normal prostate tissue, as revealed by methylation microarray analysis of tumor-associated and nontumor-associated normal prostatic tissue (Yang et al., 2013a). This observation is consistent with the outgrowth of tumor clones originating from stem cells and clonal benign and PIN tissue. Clinical studies have shown that quantitative methylation analysis of the *GSTP1*, *APC*, *PTGS2*, *RASSF1α*, *MDR1*, *p16*, and *MGMT* genes can improve sensitivity and specificity for the diagnosis of cancer (Dobosy et al., 2007). **These observations have clinical utility, as demonstrated by a study that showed that the methylation status of *GSTP1*,**

***APC*, and *RASSF1a* on prostate needle biopsy can be used to predict the likelihood of cancer on subsequent biopsy with a negative predictive value of 90%** (Stewart et al., 2013)**.**

TCGA defined four distinct subtypes of DNA methylation in primary prostate cancers. About one-third of *ERG*-positive tumors were hypermethylated, with about twice the number of hypermethylated loci as the other subtypes (Fig. 148.11), with methylation patterns distinct from *ETV1*-positive and *ETV4*-positive tumors. The results suggest that tumors characterized by *ETS*-family fusions can be further subdivided by epigenetic changes into two subclasses that carry distinct biologic behavior. *SPOP*- and *FOXA1*-mutant tumors had homogeneous epigenetic profiles, similar to *ETV1*-positive and *ETV4*-positive tumors. As noted earlier, *IDH1*-mutant tumors had the highest levels of hypermethylation.

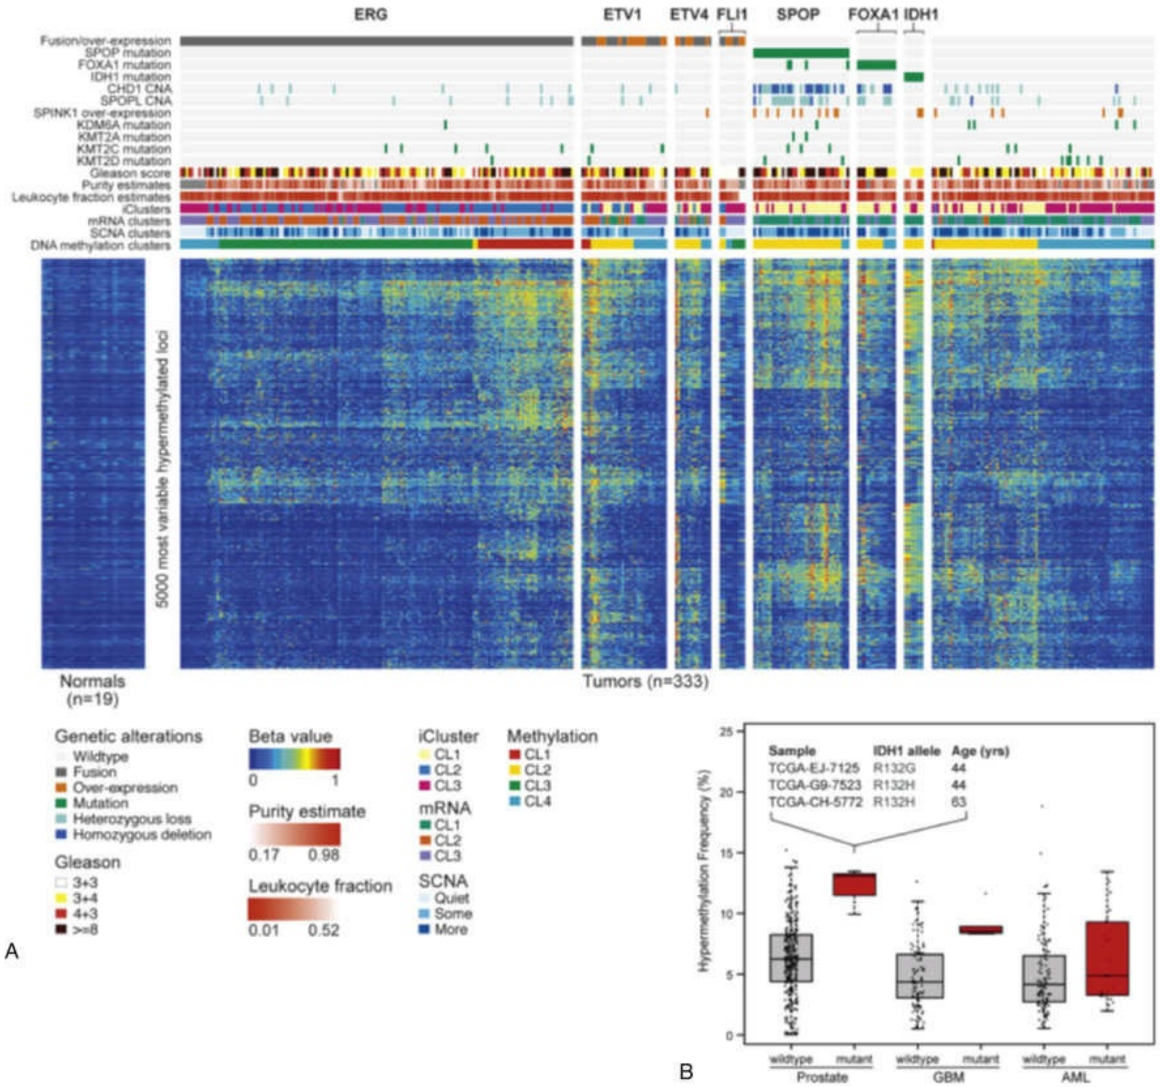

FIG. 148.11 Distinct hypermethylation patterns in prostate cancer across molecular subtypes. (A) Primary prostate cancers show diverse methylation changes compared with normal prostate samples *(left).* ERG-positive tumors had a high diversity of methylation changes, with a distinct subgroup (cluster 1) nearly unique to this group. *SPOP* and *FOXA1* mutant tumors also exhibited global hypermethylation. (B) *IDH1*-mutant prostate cancers, which are associated with younger age, are among the most hypermethylated tumors, similar to that seen in gliomas and acute myeloid leukemia. (Reproduced with permission from Cancer Genome Atlas Research Network. The molecular taxonomy of primary prostate cancer. *Cell* 163[4]:1011–1025, 2015.)

Chromatin remodeling and histone post-translational modifications are also important epigenetic mechanisms of gene deregulation in prostate cancer. A number of histone-modifying enzymes have been reported to be altered, the best characterized of which is the histone methyltransferase polycomb protein *EZH2*. *EZH2* overexpression is correlated with promoter hypermethylation leading to gene silencing and is associated with higher proliferation rates and disease recurrence (van Leenders et al., 2007). Other histone modifiers, including histone deacetylators (HDACs), are upregulated in prostate cancer and are targets for both prevention and therapy using agents that can inhibit or reverse their effects. Histone acetylation also appears important in regulating AR function (Jerónimo et al., 2011).

Newly discovered forms of noncoding RNA species, including miRNA and lncRNA, affect post-transcriptional gene expression. miRNAs are typically 18 to 25 nucleotides long and act by binding to and thereby silencing messenger RNAs (mRNAs) that have complementary sequences (Malik and Feng, 2016). lncRNAs are species of more than 200 nucleotides that regulate gene expression by a variety of mechanisms. While numerous miRNAs have been demonstrated to affect the cell cycle, intracellular signaling, DNA repair, and adhesion/migration in prostate cancer, their main effects seem to be on suppression of apoptosis and AR regulation (Catto et al., 2011). **lncRNAs are emerging as molecules with fundamental biologic and clinical importance in prostate cancer:** PCA3 is a lncRNA that can be detected in urine after a DRE and has clinical utility both in cancer detection and deciding on the need for subsequent biopsy after an initial negative biopsy (Marks et al., 2007). Prostate cancer–associated ncRNA Transcript 1 (PCAT1) is upregulated in early-stage prostate cancer and represses the DNA repair gene *BRCA2*, leading to a functional deficiency in homologous recombination and resulting in sensitivity to PARP inhibitors and radiation. PCAT1 also promotes prostate cell proliferation through the upregulation of *c-MYC*. (Prensner et al., 2014a,b). Expression levels of the lncRNA *SChLAP1* have been shown to be associated with metastasis and prostate-cancer–specific mortality after radical prostatectomy (Prensner et al., 2013). PRNCR1 (prostate cancer noncoding RNA 1) lncRNA has been isolated from the “gene desert” region of 8q24 (the germline susceptibility locus most repeatedly identified in GWAS) is overexpressed in PIN and cancer, and causes ligand-independent activation of the AR (Chung et al., 2011; Yang et al., 2013b).

There is a complex interplay between the described epigenetic mechanisms in prostate cancer. For example, several miRNAs are known to be regulated through promoter methylation or hypomethylation, and some miRNAs control the expression of histone-modifying enzymes. At another level of complexity, both miRNAs and EZH2 independently interact with the *ETS*-gene fusion axis

(Jerónimo et al., 2011).

Androgen Receptor

As discussed earlier, germline polymorphisms of the AR are linked epidemiologically to prostate cancer risk. **The role of AR is well established in the progression of castrate-resistant disease, which is characterized by AR point mutations and amplification, alternative splice mechanisms, and ligand promiscuity, which makes the AR constitutively active, exquisitely sensitive to low levels of intratumoral androgen, or both** (Scher and Sawyers, 2005)**. While these lesions are absent in early-stage disease, dysregulation of the AR signaling axis may occur earlier in disease progression,** involving activating mutations in *FOX1A* and amplification of *NCOA2* that increase androgen-dependent proliferation (Barbieri and Tomlins, 2014). Whole-genome analysis has demonstrated that rearrangement break points are more common near AR binding sites, suggesting AR-mediated transcription brings together distant genomic loci and predisposes to genomic rearrangements (Berger et al., 2011). **TCGA found that AR transcriptional activity is present in all primary tumors, but with activity that varies according to molecular subtype, with variable activity in ETS-positive tumors and highest activity in SPOP-positive and FOXA1-positive tumors** (Cancer Genome Atlas Research Network, 2015)**. TCGA also found that several AR splice variants, including AR-V7, can be detected at low levels in primary tumors.** Androgen signaling promotes corecruitment of AR and topoisomerase II beta (TOP2B) to sites of *TMPRSS2-ERG* genomic break points, triggering DNA double-strand breaks and resulting in de novo production of *TMPRSS2-ERG* fusion transcripts (Haffner et al., 2010). **These observations suggest that AR-mediated transcriptional activity acts as an early driver of genomic rearrangements in prostate cancer, and reinforces AR-mediated transcription as a critical signaling pathway in both primary and advanced disease** (Barbieri and Tomlins, 2014).

DNA Repair Defects and Other Alterations

Defects in DNA repair pathways were found in 19% of primary tumors in TCGA, including mutations in *BRCA2, CDK12, ATM, FANCD2,* and *RAD51C* (Cancer Genome Atlas Research Network, 2015). These mutations may serve as markers of therapies that target DNA repair, recently shown to be active in men with somatic *BRCA* mutations in castrate-resistant disease (Mateo et al., 2015). Alterations in the *PI3K/mTOR* pathway were also frequent, with 17% of tumors containing *PTEN* alterations and rare activation of *PIK3CA, PIK3CB, AKT1,* and *MTOR*, and of several small GTPases including *HRAS* and *BRAF*. These alterations also serve as potential therapeutic targets.

Differences Between African-Americans and Caucasians

As noted earlier, African-American men have the highest worldwide incidence of and mortality caused by prostate cancer. While the underlying reason for this is unknown, it is likely multifactorial (including diet, social determinants, and access to care), and recent molecular genetic data suggest that it is explained in part by differences in tumor biology (Faisal et al., 2016) (Fig. 148.12). **Multiple studies have observed (1) fewer *ERG*-positive tumors; (2) more frequent overexpression of *SPINK1*; (3) more frequent *ERG-/ETS-/SPINK1*-negative tumors; and (4) fewer *PTEN* mutations in African-American men than in European-American men** (Faisal et al., 2016; Khani et al., 2014, Tomlins et al., 2015). One additional study demonstrated differential expression of six molecular markers (including ERG) in primary tumors from prostatectomy specimens between African-Americans and European-Americans that predicted for adverse pathology (Yamoah et al., 2015). The emerging data suggest measurable biologic differences in the pathogenesis of prostate cancer in these men, and efforts are ongoing to understand whether they have clinically meaningful implications for screening and treatment.

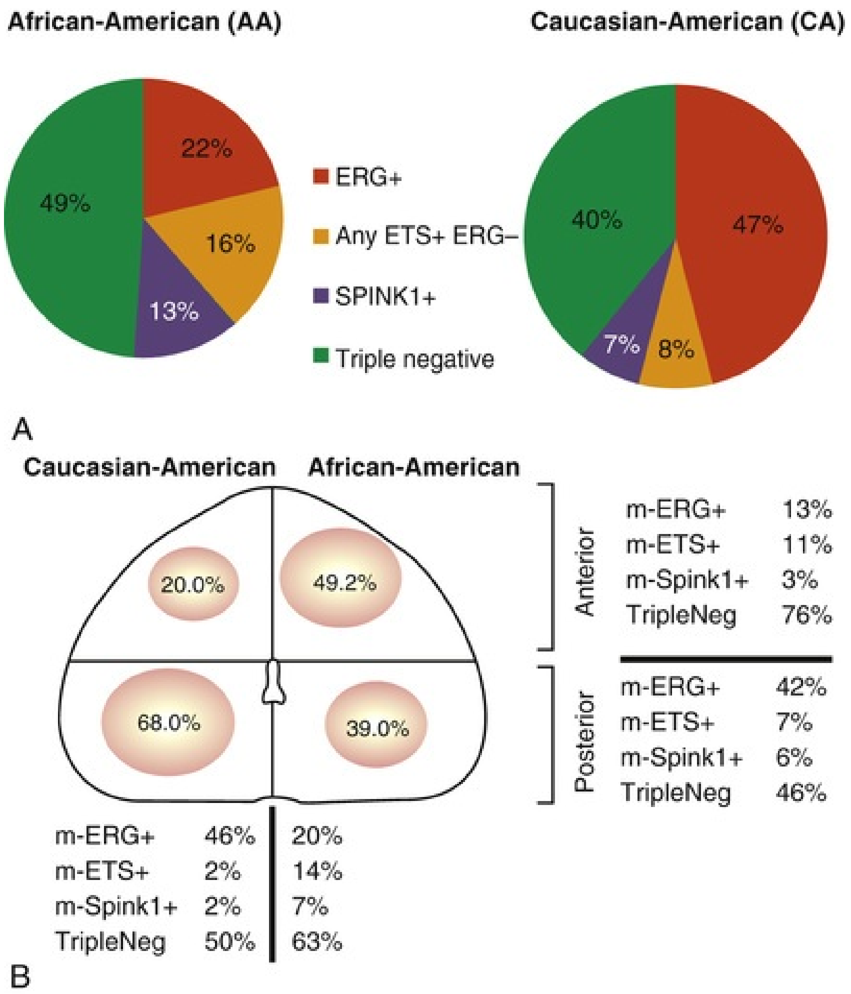

FIG. 148.12 Molecular and spatial differences in prostate cancers from African-American and Caucasian-American men. (A) Distribution of genomic alterations by race; (B) tumor location by race with associated genomic changes. (Reproduced with permission from Faisal FA, Sundi D,, Tosoian JJ, et al. Racial variations in prostate cancer molecular subtypes and androgen receptor signaling reflect anatomic tumor location. *Eur Urol* 70[1]:14–17, 2016.)

An Integrated Model of Prostate Cancer Tumorigenesis

A comprehensive, integrated model of the genetic and environmental events that underlie the genesis and progression of prostate cancer from germline susceptibility to castrate-resistant metastatic disease is now emerging (see Figs. 148.8 and 148.9). Early events in genetically susceptible men include environmental insults such as diet and infection that result in inflammatory insults to DNA integrity in prostate epithelium. Early genetic events that fuel the progression of precursor lesions to early cancers include *ETS* fusion or mutations in *SPOP, FOXA1, or IDH1* in *ETS*-negative tumors. Alterations in DNA repair pathways and mutations in classical tumor suppressors follow, leading to inactivation of the *PI3K/PTEN/Akt* pathway and disease progression, culminating in the multifaceted dysregulation of AR function and signaling that leads to lethal disease. In TCGA, relative to metastatic disease, primary prostate cancers had a lower burden of copy-number alterations and mutations, and the distribution of molecular subtypes was similar, with the notable exception that IDH1-mutant tumors seem limited to primary cancers (Cancer Genome Atlas Research Network, 2015). Similar to the overall burden of genomic alterations, many genes and pathways have increased alteration rates in metastatic disease, especially the DNA repair pathways. Amplification and mutations of AR, commonly seen in metastatic disease, were absent in primary tumors. While many gaps in understanding this process still exist, we are on the threshold of having a detailed molecular map with temporal sequencing that will allow advances in the most important clinical challenges facing the field—improved identification of those at risk for disease development who will be the best candidates for chemoprevention; improved identification of those with indolent tumors who can avoid or delay initial therapy; biologic measures of disease progression that identify those who need therapy; and targeted molecular therapy for those with progressive disease.

Chemoprevention

Rationale

The ubiquity and mortality of prostate cancer make it an attractive target for chemoprevention, defined as the use of natural or synthetic agents that reverse, suppress, or prevent the carcinogenic process, thereby preventing the development of clinically evident cancer. **The goal of chemoprevention is to decrease the incidence of a given cancer, simultaneously reducing both treatment-related side effects and mortality. Primary chemoprevention targets the general population of healthy individuals at risk to prevent the development of prostate cancer. Secondary prevention strategies target individuals with premalignant lesions with the goal of preventing progression to frank cancer. Tertiary prevention aims to prevent the development of a second primary cancer in an affected individual.** Numerous epidemiologic observations suggest associations between dietary and lifestyle factors and the risk for developing prostate cancer. **The clinical rationale for chemoprevention is based on the fact that the risk factors for prostate cancer (age, ethnicity, and family history) are not modifiable (with the exception of PSA screening); the biologic rationale is that premalignant changes appear as long as 20 to 30 years before the appearance of cancer** (Nelson et al., 2003; Umar et al., 2012)**, providing an opportunity to intervene before a malignancy is established using lifestyle changes (dietary alterations, smoking cessation, exercise) or by chemoprevention.** The challenge of chemoprevention is finding an effective intervention that has acceptable toxicity, and identifying a population of individuals at sufficiently increased risk for developing prostate cancer for which chemoprevention is appropriate and cost-effective (see Fig. 148.10).

An effective primary prevention strategy would spare many men the burden of diagnosis and cure and further reduce overdiagnosis and overtreatment associated with screening, augmenting recent gains in the use of more accurate of screening tests than PSA and the growing use of active surveillance. When combined with aggressive early detection and treatment, chemoprevention also has the potential to reduce the mortality from prostate cancer. Several large, controlled, randomized trials that tested the ability of various agents to prevent prostate cancer have been reported in recent years.

Pharmacologic Agents

5α-Reductase Inhibitors

Prostate Cancer Prevention Trial

The PCPT was the first large-scale primary chemoprevention trial in men at risk for prostate cancer (Thompson et al., 2003). The study randomized 18,882 men 55 years of age and older with a normal DRE and a PSA less than or equal to 3.0 ng/mL to finasteride 5 mg or placebo daily for 7 years. **The rationale for finasteride (a selective type 2 5α-reductase inhibitor [5ARI]) as a chemopreventive agent was based on the absence of prostate cancer in men with congenital deficiency of 5α-reductase (the enzyme that converts T to DHT) and the critical role of androgens in the development of prostate cancer.** Biopsy was recommended at the end of study for all participants or “for cause” if men had a PSA level greater than or equal to 4 ng/mL (adjusted for the effect of finasteride) or an abnormal DRE. The primary end point was the prevalence of prostate cancer during the 7 years of the study. Ultimately, 9060 (48%) participants were evaluable for the primary end point.

The main finding of PCPT was a 25% (95% CI, 19 to 31) reduction in the period prevalence of prostate cancer in men taking finasteride (18.4%) compared with placebo (24.4%). The relative benefit of finasteride versus placebo in reducing the risk for prostate cancer was apparent across all groups as defined by age, ethnicity, family history of prostate cancer, and PSA at study entry, with HRs between 0.66 and 0.81. The risk reduction in the finasteride arm was seen in both clinically apparent tumors (those diagnosed “for cause” because of an elevated PSA or abnormal DRE) and end-of-study biopsies (men with PSA <4.0 ng/mL and normal DRE at study termination). **However, a significant increase in the prevalence biopsy Gleason score 7 to 10 cancers was observed in men receiving finasteride (280 [37%]) compared with placebo (237 [22%]), particularly for biopsy Gleason score 8 to 10 cancers (90 [12%] in the finasteride arm vs. 53 [5%] in the placebo arm).**

A number of relevant observations can be made about the results of the trial. Most surprising was the 24.4% prevalence of prostate cancer in the placebo arm, four times higher than the 6% assumed for the trial design. This discrepancy can be explained by the fact that the 6% assumption was based on SEER incidence estimates, which are derived from clinically evident cases and not on the prevalence in men undergoing biopsy with PSA less than 4 ng/mL and normal DRE. The incidence of clinically evident cancers detected “for cause” by elevations in PSA or abnormal PSA was 7.2% at 7 years, similar to the cancer incidence in the screening arms of the ERSPC (8.2%) and PLCO (7.4%) (Andriole et al., 2009; Schröder et al., 2009). **Another observation was a marked effect of finasteride on the prevalence of biopsy Gleason score 2 to 6 tumors, no effect on the prevalence of biopsy Gleason score 7 tumors, and an increase in the prevalence of biopsy Gleason score 8 to 10 tumors**. The higher incidence of biopsy Gleason score 8 to 10 tumors was restricted to those men undergoing “for cause” biopsy, though this is partly explained by the low prevalence of these high-grade cancers in men with PSA less than 4.0 ng/mL and normal DRE (20 of 3652 in the finasteride arm vs. 8 of 3820 in the placebo arm).

Secondary analyses of PCPT have demonstrated an overall improved sensitivity of DRE, and a higher accuracy of PSA for the diagnosis of prostate cancer in the finasteride arm (Thompson et al., 2006, 2007b)**. Finasteride-treated glands were also 28% smaller on average compared with those in the placebo arm, and data suggest that having a smaller prostate enhances the detection of cancer, and proportionately more diagnosed cancers are high-grade** (Kulkarni et al., 2006). These effects of finasteride on the detection of prostate cancer should bias PCPT in favor of the placebo arm and lead to a greater detection of all grades of prostate cancer with finasteride, further strengthening the results of the trial.

There are two areas of continued debate over the results of the PCPT. The first is that critics argue that finasteride prevents insignificant cancers and does little to prevent “potentially lethal” cancers. This criticism is based on the fact that the incidence of cancers in the control arm (24.4%) was significantly higher than a man's lifetime risk for developing prostate cancer (18%) and four times higher than the cancer incidence in screening trials over a similar period. Finasteride also reduced the prevalence of low-grade cancers and did not appear to reduce the risk for high-grade cancers. **However, in a secondary analysis of 93.4% of biopsy specimens that were subject to central pathology review, the rate of insignificant cancers (as defined by the Epstein criteria)** (Epstein et al., 1994) **among the biopsy Gleason 2 to 6 cancers detected in the finasteride (38%) and placebo arms (36%) was not significantly different** (Lucia et al., 2008).

The second question still under debate is whether finasteride induces the development of high-grade or aggressive cancers. Androgen-deprivation therapy is known to change the appearance of prostatic epithelium in a way that could bias interpretation (Civantos et al., 1996). Thus, the apparent increase in high-grade cancers in men treated with finasteride may be an artifact of these morphologic changes. However, when this was examined in PCPT, **there appeared to be no morphologic effect of finasteride on prostate cancer grading when specimens were reviewed by a panel of expert pathologists blinded to the treatment arm** (Lucia et al., 2008). Another potential explanation for the observed increase in high-grade tumors in the finasteride group is ascertainment bias. As stated earlier, finasteride has been shown to increase the sensitivity of PSA and DRE, and decrease prostate volume by 28%, leading to a higher probability of finding the high-grade component of cancer (among men with Gleason 7 to 10 cancer) on biopsy. **Indeed, the rate of upgrading from biopsy Gleason score 2 to 6 to pathologic Gleason score 7 to 10 among men treated by radical prostatectomy was higher in the placebo arm compared with the finasteride arm** (Lucia et al., 2008).

If finasteride induces high-grade cancers, one would expect a higher proportion of cancers with adverse features by biopsy criteria or at radical prostatectomy in the finasteride arm. **Among Gleason 7 to 10 cancers, use of finasteride was associated with more favorable features of tumor extent on biopsy specimens compared with placebo, including percent of positive cores (34% vs. 38%, *P* = 0.016), aggregate linear tumor length (7.6 vs. 9.2 mm, *P* = 0.13), bilaterality (23% vs. 31%, *P* = 0.046), and perineural invasion (14% vs. 20%, *P* = 0.07)** (Lucia et al., 2007, 2008). Among the 528 men who were treated by radical prostatectomy, no significant difference in the rate of extraprostatic extension, seminal vesicle invasion, or lymph node metastasis was observed between the two arms, and there were fewer pathologic Gleason 7 to 10 cancers among men treated with finasteride versus placebo (89 vs. 105).

In a secondary analysis of PCPT that adjusted for the effects of finasteride on the detection of prostate cancer, the adjusted prostate cancer rates were estimated to be 21.1% for the placebo group and 14.7% in the finasteride group, a 30% risk reduction for all cancers (HR 0.70; 95% CI, 0.64 to 0.76) and a nonstatistically significant 14% increase in high-grade cancer (Redman et al., 2008)**. Accounting for the increased probability of upgrading to pathologic Gleason 7 to 10 cancer at radical prostatectomy among men with biopsy Gleason 2 to 6 cancers in the placebo arm, the investigators estimated the rate of true high-grade cancer to be 6% in the finasteride arm and 8.2% in the placebo arm, representing a 27% relative**

risk reduction in the rate of true high-grade cancers in men treated with finasteride (HR 0.73; 95% CI, 0.56 to 0.96). Using different methodology in an independent analysis, Pinsky et al. (2008) concurred that the rate of true high-grade disease may have been lower in the finasteride group compared with the placebo group.

In a long-term follow-up study of all 18,880 men enrolled in the PCPT, some of whom had survival information out to 18 years, no significant differences between treatment groups was observed for overall survival at 15 years (78% vs. 78.2%; unadjusted HR 1.02; 95% CI, 0.97 to 1.08; *P* = 0.5) or among 2401 men with prostate cancer at 10 years (79.3% vs. 79.5%; adjusted HR 1.01; 95% CI, 0.85 to 1.2; *P* = 0.9) (Thompson et al., 2013) **(Fig. 148.13). The absence of important survival differences between treatment arms (and among those with cancer) suggest that the apparent higher incidence of higher-grade cancers in men treated with finasteride does affect survival.** While finasteride did not appear to reduce overall mortality, it was associated with a 43% reduction in the risk for low-grade cancers. Using survival data from the PLCO trial to project prostate cancer mortality from incidence patterns, Pinsky et al. (2013) estimated that use of a 5ARI had no impact on prostate cancer mortality based on the PCPT data using unadjusted (HR 1.02; 95% CI, 0.9 to 1.2) and adjusted analyses (HR 0.9; 95% CI, 0.8 to 1.1) for the effects of 5ARIs on cancer detection. Several other cohort studies have shown no effect on prostate cancer–specific or overall mortality in men taking 5ARIs (Azoulay et al., 2015; Wallner et al., 2016). Together, these studies suggest the apparent increase in high-grade cancers with the use of 5ARIs does not translate into impacts on survival or mortality from prostate cancer or other causes.

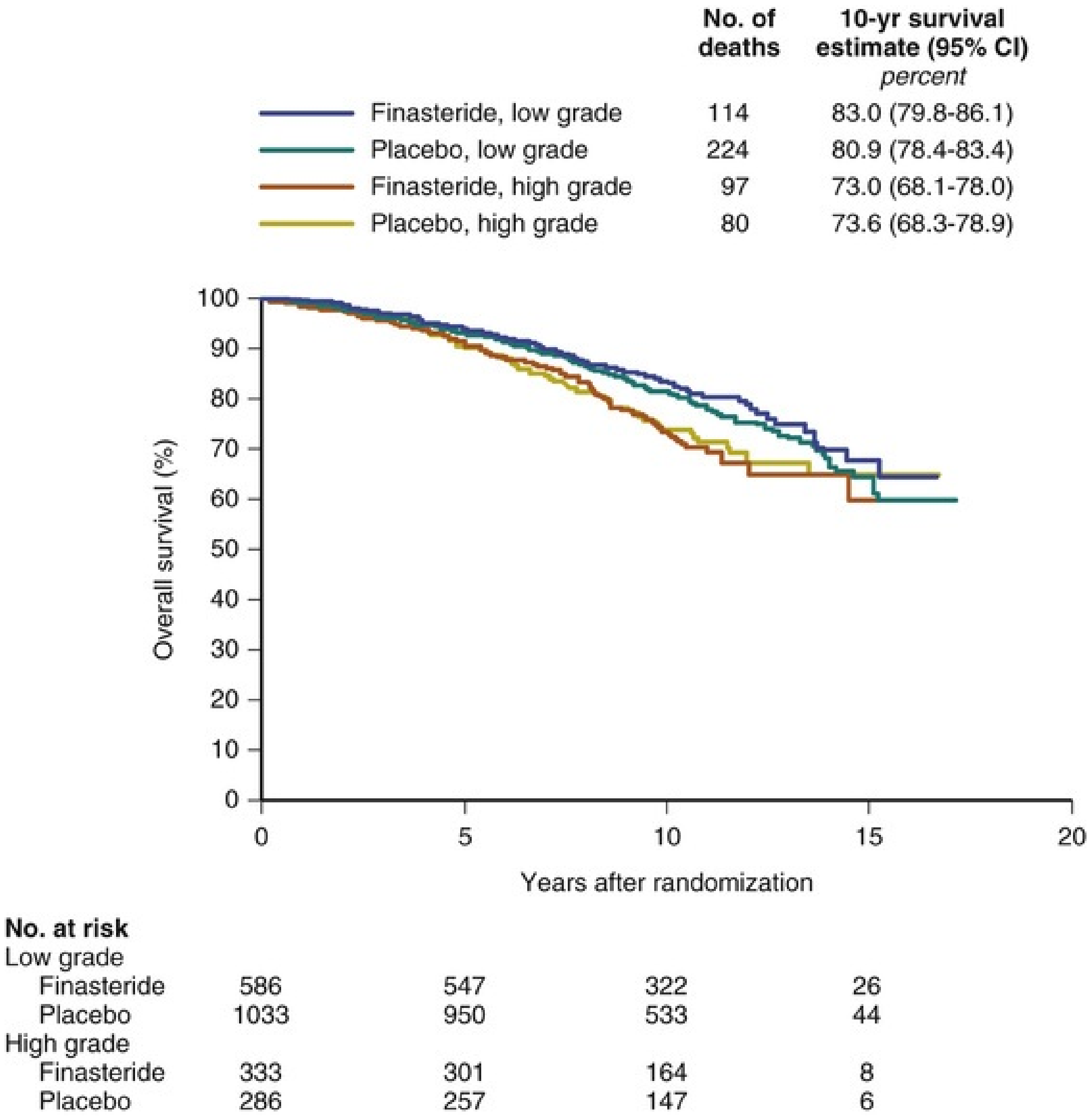

FIG. 148.13 Overall survival of men with prostate cancer, according to cancer grade, in the Prostate Cancer Prevention Trial. (From Thompson IM, Goodman PJ, Tangen CM, et al. Long-term survival of participants in the Prostate Cancer Prevention Trial. *N Engl J Med* 369(7):603–610, 2013; Figure 3.)

In addition to the prevention of prostate cancer, 5ARIs have other benefits which need to be considered. As mentioned earlier, finasteride improves the sensitivity of PSA and DRE for prostate cancer detection (Thompson et al., 2006, 2007b). Furthermore, finasteride reduced the risk for prostatitis, acute urinary retention, and the need for surgical intervention. On the other hand, adverse effects more common with finasteride than placebo include impaired sexual or erectile function and endocrine effects. Pooled data from randomized trials indicate absolute differences of 2% (95% CI, 1 to 2) for gynecomastia, 3%

(95% CI, 1 to 6) for decreased libido, 4% (95% CI, 1 to 8) for erectile dysfunction, and 4% (95% CI, 8 to 17) for reduced volume of ejaculate (Moinpour et al., 2007). Sexual dysfunction was also assessed in the PCPT participants during the 7-year trial period using the Sexual Activity Scale. Compared with baseline scores, over the course of 7 years finasteride was associated with a slight increase in sexual dysfunction relative to placebo. **A 20-year follow-up study showed that men in the finasteride arm experienced fewer Medicare claims for BPH-related symptoms, a slight increase in claims related to depression, and no differences compared with placebo for ischemic and thrombotic events (acute myocardial infarction, ischemic heart disease, thrombosis), endocrine events (diabetes, diabetes with sequelae, hypercholesterolemia, obesity, osteoporosis, fractures, any bone event), sexual dysfunction, or dementia** (Unger et al., 2016)**. These data, along with the long-term survival data, suggest that long-term finasteride use is safe.**

Reduction by Dutasteride of Prostate Cancer Events Trial

The REDUCE trial is another large-scale, randomized, placebo-controlled primary chemoprevention trial using a different 5ARI called dutasteride, which is an inhibitor of both type 1 and type 2 isoforms of 5α-reductase. Dutasteride has been shown to reduce the risk for prostate cancer in men treated for lower urinary tract symptoms related to BPH compared with placebo (Andriole et al., 2004b). Eligibility for the REDUCE trial included men with a prior negative prostate biopsy (6 to 12 cores) within 6 months of enrollment who were 50 to 75 years of age and had a baseline PSA 2.5 to 10 ng/mL and a prostate volume less than or equal to 80 cc. The primary end point of the REDUCE trial was the prevalence of cancer on study-mandated 10-core prostate biopsies performed at 2 and 4 years after randomization.

The REDUCE trial accrued 8231 men, of which 6726 (82.6%) underwent at least one biopsy and 1516 (22.5%) were diagnosed with prostate cancer. **Dutasteride reduced the risk for prostate cancer over 4 years by 23% (858 in the placebo arm vs. 659 in the dutasteride arm, $P < 0.001$) and showed similar reductions in years 1 to 2 and years 3 to 4** (Andriole et al., 2010). There was no significant difference between groups in terms of cancer reduction on protocol-independent (“for-cause”) biopsies (17% in both arms). As with finasteride in the PCPT, the benefit of dutasteride in prostate cancer risk versus placebo was apparent across all subgroups, including age, family history, and PSA level at study entry (relative risk reduction 22% to 32%). While there was no difference in the detection of Gleason 7 to 10 cancers throughout the study ($P = 0.8$), including Gleason 8 to 10 cancers (29 in dutasteride arm vs. 19 in the placebo arm, $P = 0.15$), there was an increased risk for Gleason 8 to 10 cancers during years 3 to 4 of the study (1 in placebo vs. 12 in dutasteride, $P = 0.003$), although no additional Gleason 8 to 10 cancers were seen 2 years off-study among 2751 men assessed (Grubb et al., 2013). There were no deaths from prostate cancer reported during the study, and there were no significant differences between treatment arms among detected cancers in terms of percentage or number of positive cores or tumor volume, even among Gleason 7 to 10 cancers. The rate of HGPIN was also significantly lower among men receiving dutasteride (3.8% vs. 4.9%, $P = 0.04$). Dutasteride also demonstrated beneficial effects on BPH outcomes (acute urinary retention and BPH-related surgery) and was generally well tolerated (15% drug-related adverse events in the placebo arm vs. 22% in the dutasteride arm). Dutasteride also appeared to have beneficial effects on PSA as a marker of prostate cancer (Marberger et al., 2012).

Summary: PCPT and REDUCE

The PCPT and REDUCE trials confirm the consistency of effect of 5ARIs at reducing the risk for prostate cancer, with a similar magnitude of risk reduction across all subgroups. The fact that the results of the REDUCE trial were congruent with those of the PCPT in the magnitude of risk reduction, benefits on BPH end points, and minimal toxicity suggest that 5ARIs represent an effective primary prevention strategy. In 2010, the Oncology Drug Advisory Committee of the FDA convened to assess the evidence in support of 5ARI as chemoprevention agents for prostate cancer. As part of its review, all biopsy specimens from the PCPT and the REDUCE trial that showed prostate cancer were subject to central pathology review and regraded using the modified Gleason scale. **The FDA reassessment showed a significant increase in Gleason 8 to 10 cancers across both trials (relative risk 1.7; 95% CI, 1.2 to 2.3), suggesting that one additional man would be diagnosed with high-grade prostate cancer to avert 3 to 4 low-grade cancers for every 150 to 200 men treated with a 5ARI** (Theoret et al., 2011). The committee believed that the post-hoc exploratory analyses of the PCPT and REDUCE trials did not provide convincing evidence that the increased incidence of high-grade cancer observed in both trials can be dismissed. **The FDA concluded that 5ARIs did not have a favorable risk-benefit profile for the chemoprevention of prostate cancer.** Despite multiple analyses suggesting that detection bias accounted, at least in part, for the observed increase in the rate of high-grade tumors with 5ARIs, concern regarding this risk has all but eliminated the use of 5ARIs for prostate cancer prevention in common urologic practice. Several cost-utility analyses have, however, suggested that chemoprevention with a 5ARI may be cost-effective in populations at high risk (Kattan et al., 2011; Svatek et al., 2008, 2011), and, as noted earlier, long-term follow-up of the PCPT and several cohort studies have demonstrated no impact on long-term mortality in men taking 5ARIs.

Toremifene Citrate

Toremifene citrate is a modulator of the ER and is FDA-approved for the treatment of breast cancer. In vitro studies in prostate cancer have shown that low-dose toremifene selectively inhibits ER-α, which serves as a mediator of growth-stimulatory signal transduction and has a direct antiproliferative effect through ER-β. **A randomized trial in 1467 men with HGPIN failed to show a reduction in prostate cancer incidence at 3 years among those receiving toremifene citrate 20 mg daily vs. placebo, even among select high-risk groups** (Taneja et al., 2013).

Other Pharmacologic Agents

Interest in metformin as a chemopreventive agent is based on epidemiologic evidence showing a link between obesity, metabolic syndrome, and high circulating insulin levels with the development of various cancers. **Epidemiologic studies on the risk for prostate cancer in men using metformin have been mixed, with some showing no effect and others suggesting a benefit** (Chen et al., 2017; Häggström et al., 2017). Statins are widely used cholesterol-lowering drugs and are hypothesized to play a role in the prevention of cancer by inhibiting inflammation, angiogenesis, altering steroid-hormone biosynthesis or metabolism, cell cycle regulation, or promoting apoptosis in tumor cells (Murtola et al., 2008). **A recent meta-analysis of 27 observational studies concluded that satin use reduces the overall risk for**

prostate cancer by about 7% and the risk for higher grade or advanced cancer by 20% (Bansal et al., 2012)**. Neither metformin or statins have been tested in controlled intervention trials for their potential ability to reduce prostate cancer risk.**

Vitamins and Micronutrients

Selenium and Vitamin E

The Selenium and Vitamin E Cancer Prevention Trial

The SELECT was a randomized, placebo-controlled, population-based primary chemoprevention trial designed to test the efficacy of selenium and vitamin E alone and in combination in the prevention of prostate cancer (Lippman et al., 2005). The rationale for using selenium was based on a secondary analysis of the Nutritional Prevention of Cancer Trial of oral selenized yeast for nonmelanoma skin cancer in which men randomized to selenium versus placebo had a 65% reduction in prostate cancer incidence over a mean follow-up of 4.5 years (Clark et al., 1996). The rationale for vitamin E was based on the Alpha-Tocopherol, Beta-Carotene Cancer Prevention Trial (ATBC) for lung cancer incidence and mortality in which male smokers were randomized to α-tocopherol (50 mg daily) and beta-carotene (20 mg daily) alone or in combination versus placebo (ATBC Prevention Study Group, 1994). On secondary analysis, the ATBC trial found a statistically significant 32% reduction in prostate cancer incidence in those receiving α-tocopherol (Albanes et al., 1995).

The SELECT randomized 35,533 men to four treatment arms (selenium + placebo, vitamin E + placebo, selenium + vitamin E, and placebo + placebo) (Lippman et al., 2009). Eligibility criteria included age 50 years and older for African-Americans, age 55 years and older for Caucasians, a DRE not suspicious for cancer, serum PSA less than or equal to 4 ng/mL, and normal blood pressure. The primary end point was biopsy-confirmed prostate cancer, although the indications for biopsy were not dictated by protocol. **Although the study duration was planned for 12 years, the study was closed after an interim analysis at 7 years because the data convincingly demonstrated no effect on the risk for prostate cancer by either agent alone or in combination, and no chance of a beneficial effect of the hypothesized magnitude with continued supplementation** (Lippman et al., 2009)**. Hazard ratios for prostate cancer were 1.13 (99% CI, 0.95 to 1.13) for vitamin E, 1.04 (99% CI, 0.87 to 1.24) for selenium, and 1.05 (99% CI, 0.88 to 1.25) for selenium and vitamin E. A follow-up study that included an additional 54,464 person-years showed that dietary supplementation with vitamin E**

actually increased the risk for prostate cancer (HR 1.17, 95% CI, 1.004 to 1.36, *P* = 0.008) (Klein et al., 2011) **(Fig. 148.14).**

FIG. 148.14 Cumulative incidence of prostate cancer detection over time by intervention group in the Selection and Vitamin E Cancer Prevention Trial (SELECT). Those taking vitamin E alone had a 17% increased risk of prostate cancer compared with placebo (HR = 1.17; 99% CI, 1.004 to 1.36, *P* = .008); rates of prostate cancer in the selenium alone arm and selenium plus vitamin E arm were not different from placebo (HR = 1.09; 99% CI, 0.93 to 1.27; *P* = .18 and HR = 1.05; 99% CI, 0.89 to 1.22, *P* = .46, respectively). (Data from Klein EA, Thompson IM Jr, Tangen CM, et al. Vitamin E and the risk of prostate cancer: the Selenium and Vitamin E Cancer Prevention Trial (SELECT). *JAMA* 306(14):1549–1556, 2011; Figure 2.)

The absence of a beneficial effect of these micronutrients on prostate cancer risk was also observed in other randomized trials (Algotar et al., 2013; Gaziano et al., 2009). Two randomized trials have evaluated the effect of selenium, vitamin E, and/or soy on the risk for prostate cancer among men with evidence of HGPIN on prior biopsy. The Southwest Oncology Group 9917 randomized 423 men with HGPIN to selenium 200 mcg/day versus placebo and found no difference in the 3-year risk for prostate cancer (36% vs. 37%, *P* = 0.7), although men with the lowest baseline plasma selenium levels experienced a nonstatistically significant risk reduction (Marshall et al., 2011). A similar trial from the National Cancer Institute of Canada randomized 303 men with HGPIN to daily soy (40 g), vitamin E (800 U), and selenium (200 mcg) versus placebo and found no significant reduction in prostate cancer risk at 3 years (HR 1.03, 95% CI, 0.7 to 1.6; *P* = 0.9) (Fleshner et al., 2011).

Together, these results suggest that neither selenium nor vitamin E should be used in the hope of preventing prostate or other cancers. The 17% increased prostate cancer risk associated with vitamin E in the SELECT demonstrates the potential for seemingly innocuous yet biologically active substances to cause harm. The reasons why these trials failed to confirm the presumed cancer-preventive activity of micronutrients are uncertain. A possible explanation is that men in earlier trials were relatively deficient of these micronutrients compared with those enrolled in the more recent trials. **Thus, micronutrients may have cancer-preventive activity in deficient individuals but have no benefit (and potentially harm) in those who are nutritionally replete.**

Conclusion

It is clear that the process of prostate carcinogenesis is complex. The interplay of constitutional, behavioral, and molecular and environmental factors against the backdrop of various processes occurring during aging interact to set in motion a series of events that ultimately manifest through the diagnosis of prostate cancer. Complicating the understanding of this process are various confounds associated with the diagnosis of the disease in clinical trials, in the general population, and in epidemiologic studies.

Despite promising outcomes from clinical trials of 5ARIs for chemoprevention of prostate cancer, their relatively low use/enthusiasm by prostate cancer specialists and primary care practitioners despite endorsement by professional societies and subsequent failure to gain regulatory approval by government agencies highlights the challenges of developing new agents and approaches to chemoprevention. The FDA poses a substantial obstacle because of intense scrutiny over toxicity, as was seen with 5ARIs. As seen with the SELECT, the promise of micronutrients as chemopreventive agents have fallen well short of expectations, and may potentially be harmful. Future directions will require genetic and molecular approaches for identifying at-risk patients and appropriate targets for chemoprevention.

Key Points: Epidemiology

- In the United States, prostate cancer is the most common visceral malignancy in men and the third leading cause of cancer-related deaths.
- Prostate cancer mortality has declined since 1991 and for Caucasians is now lower than before PSA was introduced.
- Worldwide, prostate cancer incidence and mortality rates vary significantly among countries and regions but are highest in African-American and Jamaican men.
- PSA has induced a significant downward migration in age and both clinical and pathologic stage at diagnosis.
- PSA screening reduces prostate cancer mortality, however, the absolute effect is small relative to the number needed to screen and treat to cure a

single individual.

Key Points: Familial and Germline Genetic Influences

- Both genetics and environment are important in the origin and evolution of prostate cancer.
- Genome-wide association studies have identified multiple chromosomal loci and variant alleles in germline DNA that confer risk for developing prostate cancer.
- Because the predictive value of single loci is small, models with multiple risk loci or less common alleles with greater risk are needed for individual risk prediction.
- *HOXB13* and *BRCA* are two genes that substantially increase individual risk. *BRCA*-related tumors present with more aggressive clinical features.

Key Points: Inflammation and Infection

- Chronic inflammation leading to cellular hyperproliferation to replace damaged tissue appears to contribute to the development of prostate cancer.
- Both genetic and histologic observations suggest that compromised cellular defenses against inflammatory oxidants are important in prostate cancer initiation and promotion.
- Inflammation may be triggered by diet, infection, estrogens, or other environmental agents.
- Histologic evidence of inflammation, as manifested by PIA, is common in prostate cancer and may represent a key pathobiologic process in its development.

Key Points: Molecular Epidemiology

- Androgen exposure of the prostate plays an important but incompletely defined role in prostate carcinogenesis.

- Long-term absence of androgen exposure protects against cancer, but a dose-response relationship between androgen levels and prostate cancer risk has not been established.
- Polymorphisms in genes encoding for the androgen receptor and various enzymes related to androgen metabolism may be important determinants of prostate cancer risk.
- Vitamin D and its interaction with its receptor modulate risk and disease aggressiveness.
- Smoking increases the risk for disease recurrence and death caused by prostate cancer.
- Obesity is associated with lower PSA, increases the risk for developing high-grade disease, and is associated with higher treatment failure rates and mortality.

Key Points: Etiology and Molecular Genetics

- The primary androgen of the prostate is dihydrotestosterone (DHT). Exposure to DHT is a prerequisite for developing prostate cancer.
- Stem cells are precursors with multilineage differentiation potential that populate epithelium of prostatic acini and are the origin of clonal epithelial expansion.
- Primary prostate cancer has a distinct molecular taxonomy characterized by seven distinct subtypes, including four defined by gene fusions and three by mutations.
- Variations in gene methylation profiles further distinguish the molecular subtypes of prostate cancer.
- The AR plays a central role in prostate cancer development and progression.
- There are distinct biologic differences in the genomics of prostate cancers of African-American and European-American men.

Key Points: Prevention

- The goal of primary chemoprevention is to decrease the incidence of a given cancer, simultaneously reducing both treatment-related side effects and mortality.

- Effective chemoprevention requires the use of nontoxic agents that inhibit specific molecular steps in the carcinogenic pathway.
- Prostate cancer is an attractive target for primary prevention because of its incidence, prevalence, treatment-related morbidity, and mortality.
- The Prostate Cancer Prevention Trial demonstrated that finasteride reduces the period prevalence of prostate cancer by 25%, with no effect on overall mortality.
- The SELECT demonstrated that neither vitamin E nor selenium prevent prostate cancer, and that use of vitamin E was associated with an increased risk for prostate cancer.

Prostate Cancer Biomarkers

Simpa S. Salami MD, MPH, Ganesh S. Palapattu MD, Alan W. Partin MD, PhD, Todd M. Morgan MD

The development and implementation of prostate cancer biomarkers have continued to expand rapidly over the past decade. In an era in which early detection based on prostate-specific antigen (PSA) has been under fire from the United States Preventative Services Task force, new markers to aid in biopsy decision have become available in the clinic. Furthermore, attention has turned from detection of any cancer to a focus on detecting clinically significant disease, often interpreted as Gleason score ≥7 cancer. In addition, biomarkers that can aid in distinguishing aggressive from indolent disease for men who have cancer continue to be sought after, and a number of these are now clinically available. However, substantial limitations exist for all of the currently available markers, and it is critical to understand the strengths and potential weaknesses for each of these before using them for clinical decision making.

Prostate cancer is one of the few malignancies with a serum-based, clinically informative biomarker. **Since its discovery in 1979 until clinical application in the late 1980s through 1990s, the PSA has evolved into an invaluable tool for detecting, staging, and monitoring prostate cancer in men.** The widespread use of PSA screening led to a dramatic increase in prostate cancer diagnoses in the mid-1990s, and the subsequent drop in prostate cancer deaths is at least partially attributable to the adoption of population-based PSA screening. **Whereas the majority of prostate cancers in the 1980s and early 1990s commonly arose through finding an abnormal digital rectal examination (DRE) or elevated PSA, or both, today most prostate cancer arises as clinically nonpalpable (stage T1c) disease with PSA levels between 2.5 and 10 ng/mL.** Widespread application of PSA screening and the long natural history of prostate cancer have also resulted in a stage migration to nonpalpable, clinically localized (stage T1c) disease to go along with the parallel reduction in mortality (Diamandis et al., 2000; Lilja, 1997; McCormack et al., 1995; Polascik et al., 1999; Pound et al., 1997, 1999; Rittenhouse et al., 1998; Stephenson and Stanford, 1997).

Although PSA screening has improved survival, however, outcomes are not the same for all PSA-detected disease (Diamandis et al., 2000; Gretzer et al., 2002; Yousef and Diamandis, 2001). Indeed the most common cause of mortality for *all* men with prostate cancer is heart disease. This is not to downplay the influence of prostate cancer on the mortality of the nearly 30,000 men who die from it annually in the United States but rather to highlight the critical need for reliable tools that allow for identification of harmful cancers.

Although PSA is the most well-known prostate cancer tumor marker, it is organ specific and not cancer specific. **There is significant overlap in serum PSA levels among men with cancer and those with benign disease. Thus even substantially elevated serum PSA levels may be due to inflammation or benign prostatic hyperplasia (BPH) rather than malignancy** (Catalona et al., 1991; Oesterling et al., 1988; Partin et al., 1990). To this end, application of PSA derivatives such as PSA density, PSA velocity, age-adjusted values, and, more recently, molecular derivatives may be used to improve clinical decisions compared with using PSA in isolation.

There are three main domains in which clinically localized prostate cancer biomarkers are needed: (1) early detection, (2) newly diagnosed prostate cancer, and (3) post-treatment. By identifying men at greatest risk of harboring harmful disease, improved early detection biomarkers could markedly reduce the group of men subjected to prostate biopsy. The cohort of men who possess an elevated PSA after an initial negative biopsy represents a particularly challenging group. After a diagnosis of prostate cancer has been made, balancing the risks and benefits of active surveillance with primary therapy as the initial management strategy is a central question. Knowledge regarding biologic behavior could drastically improve the decision-making process for a patient contemplating curative intent therapy (e.g., radical prostatectomy or radiation) or active surveillance. Finally, post-treatment biomarkers hold promise for improving our ability to make decisions regarding adjuvant or salvage therapies in men at high risk of developing metastatic disease.

Several molecular approaches have been undertaken in pursuit of finding the optimal prostate cancer biomarker. An overview of basic cellular processes starts first with a DNA sequence **(gene)** that is transcribed to mRNA **(transcript)** and then translated to a **protein** that can then carry out specific cellular functions (e.g., catalyze biochemical reactions leading to the formation of products such as

metabolites). A guiding principle of prostate cancer biomarker development is that prostate cancer cells, a priori, are different in some molecular way than their benign counterparts. Further, another important observation is that aggressive prostate cancer cells are similarly different in comparison with their more indolent counterparts. The identification and quantification of these molecular differences in tissues and bodily fluids form the basis of prostate cancer biomarker discovery.

Advances in molecular oncology and breakthroughs in laboratory techniques have exponentially expanded our repertoire of innovative tools for the discovery of novel ways of predicting the future. In this chapter, we discuss the process and phases of biomarker development, paying particular attention to scientific rationale and clinical application of blood-, urine-, and tissue-based biomarkers.

Biomarker Development

Although there are many groups now developing methods for early detection of prostate cancer, the early detection research network (EDRN) has developed a particularly robust infrastructure for biomarker development. The EDRN is a National Cancer Institute (NCI) funded program set forth with the objective to identify, develop, and validate promising biomarkers and technologies for the early detection of cancer (Clements, 1989; Schedlich et al., 1987; Srivastava, 2014; Srivastava et al., 2001). As suggested by its name, it is actually a network of academic centers working in collaboration with industry, public health groups, informatics centers, and patient advocates. The structure of the network consists of five scientific components.

The first of these are the biomarker development laboratories (BDLs), which is responsible for discovery of novel biomarkers and technologies. They identify biomarkers and participate in the early phases of validation. The biomarker reference laboratories (BRLs) facilitate the development and validation of assays that measure these new biomarkers. Without such efforts, assays results may be difficult to reproduce when deployed at a different site. The BRLs also assist in developing a more robust and efficient clinical assay. The third scientific component are the clinical epidemiological validation centers (CEVCs). These are large clinical practices with infrastructure to procure ample clinical samples and to lead clinical trials. They are responsible for procuring samples for the BDLs. The fourth component of the network is the data management and coordinating center (DMCC). This component is the spine of the network in the sense that they provide all the logistical and statistical support for all phases of development. Importantly, this EDRN component is responsible for creating a reliable, secure, and practical means by which data may be collected for network studies. The fifth and final component is the informatics center responsible for developing software for information management. As the EDRN experience grew, experts in oncology, clinical trials, biostatistics, and informatics came together and refined what is considered best practice for the development of new biomarkers (Lilja, 1997; Pepe et al., 2001; Rittenhouse et al., 1998; Young et al., 1995).

Similar to the phases of drug development, biomarker development has been broken down into a number of sequential phases. Conceptually, progression of a biomarker through each of the five phases of development indicates increasing strength of evidence in favor of its clinical application. Phase 1 consists of biomarker discovery. Although this may occur at any laboratory, the BDLs are intended to be factories of discovery along the lines of genomics, proteomics, glycomics, and metabolomics. The objective of this phase is to identify potential biomarkers and prioritize each for validation. The typical outcome of phase 1 development is a novel biomarker with some measure of test sensitivity and specificity in a subset of cancer and control subjects. In this way, a preclinical assay is moved forward into phase 2.

Phase 2 has the objective of more reliably measuring the sensitivity and specificity of the new biomarker in its ability to differentiate case status from control. Here the BRL often participates to optimize the clinical assay and assess the reproducibility of the assay in preparation for a clinical trial. It would not be unusual to see comparisons of biomarkers measured in tissue samples compared with levels from less invasive approaches such as voided urine or serum. The clinical samples deployed at this stage tend to be more representative of the target population and, as a result, biomarkers may fail at this phase if they were initially developed on an overly selected set of tissues.

In phase 3, investigators examine the ability of new biomarkers to detect preclinical disease and evaluate how much lead time is provided by the biomarker relative to clinical presentation. The criteria necessary for “a positive test” are defined in this phase. Robust studies examining the impact of covariates on biomarker expression and measurement will take place. Given the growing number of biomarkers, it would not be uncommon to see algorithms developed during this phase to support the use of panels of biomarkers as opposed to a single biomarker. The tissue repositories used for this phase are typically retrospective cohort studies in which clinical samples have been procured prospectively over time with careful annotation of clinical end points and risk factors. These subjects are usually identified before cancer is diagnosed, sometimes years in advance of diagnosis. Having completed phase 3, a new biomarker would possess a validated clinical assay and strong evidence of ability to differentiate case from control according to its clinical indication, conducted on a fairly robust sample of subjects. An understanding of factors that may affect measurement and expression of the biomarker is established, and plans are made for a prospective validation trial, that is, phase 4.

In phase 4, indications for applying a new biomarker are clearly defined according to the labeling. Potential subjects are identified for eligibility, consented, and enrolled with careful annotation of all demographic, disease, risk factors, and cancer end points. The goal of phase 4 is to quantify the performance characteristics of a biomarker in the target population of interest. This is typically done by examination of sensitivity, specificity, positive, and negative predictive values (NPVs). Secondarily, this phase also examines characteristics of cancers diagnosed using the biomarker; considers implementation feasibility and costs; and considers potential impact on overall mortality.

Unlike drug studies, in which randomized clinical trials are conducted as validation of treatment effect, biomarkers are rarely tested with such trials given the large sample sizes, long durations, and prohibitive costs (Andriole et al., 2009; Lundwall and Lilja, 1987; Schröder et al., 2009). Fortunately, robust clinical validation design specifically for biomarker discovery (prospective randomized open label, blinded end point study design, or PRoBE) has been proposed by Pepe et al. (Kumar et al., 1997; Lövgren et al., 1997; Pepe et al., 2008; Takayama et al., 1997). Use of the PRoBE design is intended to overcome spectrum bias, in which there is differential selection of cases and controls. In addition, this approach overcomes ascertainment bias, defined as inclination for differential levels of the biomarker to undergo diagnostic testing, because all subjects receive the same testing. A common strategy has been to develop prospective registries to be used for validation studies by blinding samples, which are stored at the National Cancer Institute. In this way, validation studies can be performed using large cohorts for a series of biomarkers as long as sample size is sufficient.

The ultimate objective for new biomarkers is to reduce the burden of cancer. This takes place in phase 5, cancer control studies. With deployment over time, biomarkers are expected to efficiently identify cancers earlier in the disease course, leading to greater construct validity. To achieve a successful outcome in phase 5 requires reduction in cancer mortality that can be attributed to the biomarker use without prohibitive costs or overdiagnosis. This lofty goal has been achieved by few biomarkers.

Inherently, the cost necessary to take a biomarker from phase 1 through phase 5 is often in excess of millions of dollars. A common strategy applied by the EDRN is to partner with multiple institutions and industry to fund work along the different phases with a common goal of moving biomarkers into clinical practice that are likely to improve the health of a population. It is worth pointing out that the EDRN's approach is not the only means by which biomarkers may be developed but the outline here developed by the EDRN scientists provides a rigorous framework for doing so.

Assessment of Biomarker Performance

In the previous section, we have discussed study designs as applied by the EDRN in the development and validation of biomarkers. In this section, we briefly discuss common ways by which biomarker performance may be assessed. Typically, this will be conducted using the clinical grade assay in the intended population along the indicated clinical indications. Perhaps the most common means for assessing validity is calculations of sensitivity, specificity, and accuracy. Sensitivity is defined as the proportion of individuals with the disease who have a positive biomarker test, whereas specificity is defined as the proportion of individuals without the disease who will have a negative test. Accuracy is then the sum of true positives and true negatives divided by the total population. Sensitivity and specificity are graphically summarized using the receiver operating characteristics (ROC) curve. This approach plots sensitivity on the vertical axis and 1- specificity on the horizontal axis. In doing so, the area under the curve (AUC) is a measure of the accuracy of the test. An AUC of 1 signifies an ideal test, whereas AUCs approaching 0.5 indicate a poorly performing test.

Despite widespread use, sensitivity and specificity are not intuitive to interpret in a clinical setting; therefore positive and negative predictive values are often used instead. These are calculated based on sensitivity and specificity as well as the prevalence of the disease. The definition of positive predictive value is the probability that a positive test indicates presence of cancer. Similarly, negative predictive value is the probability that the patient does not have cancer when the biomarker test is negative. In many ways, these measures are more relevant to clinical practice, and there is an increasing tendency to use these as the end point for biomarker validation trials.

In prostate cancer early detection, it is useful to think in terms of pretest and post-test probability. When new biomarkers are introduced, the natural question becomes, “How much does this add to what we already know in terms of risk prediction?” The likelihood ratio (LR) is useful in this regard because the test indicates how much a new biomarker raises or lowers the pre-biopsy probability of disease. A positive LR is calculated as the probability of a positive test in those with cancer divided by the probability of that test result in disease-free individuals. Similarly, a negative LR is calculated as the probability of a negative test result among healthy men divided by the probability of the same result among those with prostate cancer. Likelihood ratios greater than 1 indicate that the test results increases the likelihood that patient has cancer, whereas likelihood ratios less than 1 decrease the probability of the condition. In the literature, likelihood ratios greater than 5 or less than 0.2 are regarded as meaningful shifts in pretest probability.

Prostate biomarkers today are proliferating at a greater rate thanks to the many innovations in high throughput methods (Prensner et al., 2012; Takayama et al., 2001). As such, understanding the status of biomarkers with result with regard to the US Food and Drug Administration (FDA) and other approvals is helpful (Ablin et al., 1970; Füzéry et al., 2013; Kuriyama et al., 1980; Oesterling et al., 1988; Seamonds et al., 1986; Sensabaugh, 1978; Stamey et al., 1987).

FDA approval is considered to be the final end point in the development process because that indicates governmental approval for a specific indication and provides for biomarker validity and safety. Such processes are not undertaken lightly and often cost millions of dollars. Currently FDA-approved biomarkers include PSA, percent-free PSA, PHI, and PCA3. However, the FDA does not actively regulate so-called laboratory-developed tests (LDTs) that are performed in a central Clinical Laboratory Improvement Amendments (CLIA)-certified laboratory. CLIA laboratory standards established by the Centers for Medicare and Medicaid Services exist to ensure quality laboratory testing but not necessarily biomarker validity nor safety. The CLIA program examines performance characteristics of the tests with regard to laboratory precision, analytical sensitivity and specificity, reporting ranges, reference ranges, and criteria for the test systems. A CLIA-certified LDT can be offered commercially for use in the clinic, but rigorous clinical validation may or may not have taken place.

Blood-Based Biomarkers

Prostate-Specific Antigen (PSA or hK3)

Initially developed as a biomarker for monitoring prostate cancer patients after treatment, PSA continues to be a lightning rod for controversy in the setting of prostate cancer screening. Given its unique prominence, a clear understanding of PSA is needed to lay the foundation for other potential prostate cancer biomarkers. **Also known as hK3 (human kallikrein 3), PSA is a member of the kallikrein gene family** (Fig. 149.1). Originally, only three genes of this family of genes were identified: the pancreatic/renal kallikrein *(hKLK1)*, human kallikrein 2 *(hKLK2)*, and PSA *(hKLK3)* genes (Diamandis et al., 2000; Lilja, 1997; McCormack et al., 1995; Rittenhouse et al., 1998; Yu et al., 1994; Yu et al., 1994a, 1994b). Since the identification of 12 other kallikrein genes, this family of proteases now consists of 15 members and is described with a distinct nomenclature (Diamandis et al., 2000; Monne et al., 1994; Yousef and Diamandis, 2001). These proteins are all serine proteases and are located on the long arm of chromosome 19 within the region spanning q13.2-q13.4. These serine proteases have similar amino acid sequences, with hK1 expressing 60% and hK2 expressing 78% homology with PSA (Clements, 1989; Schedlich et al., 1987; Yu and Diamandis, 1995). hK2 and hK3 (PSA) are released in zymogen form from the prostatic epithelium and are found in seminal fluid as well as serum. Because they share structural homology, they can form complexes with endogenous protease inhibitors such as α_2-macroglobulin (A2M) and α_1-antichymotrypsin (ACT) (Levesque et al., 1995; Lilja, 1997; Rittenhouse et al., 1998; Young et al., 1995).

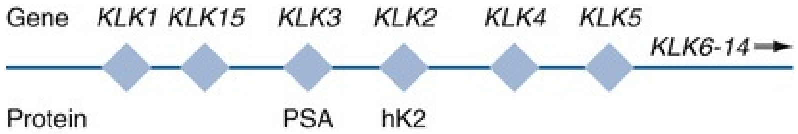

FIG. 149.1 Human kallikrein gene map. Map of the human kallikrein locus and corresponding proteins as described by Yousef and Diamandis (2001).

To understand PSA and its related derivative biomarkers, it is important to understand how PSA is processed. **PSA begins as a zymogen, termed pre-pro-PSA, that contains a 17–amino acid leader sequence** (Lundwall and Lilja, 1987; Oesterling et al., 1988; Partin et al., 1990). **Cleavage of pre-pro-PSA results in an inactive 244-amino acid proenzyme termed proPSA. Finally, cleavage of a leader amino acid sequence of proPSA by hK2 produces the active form of PSA** (Kumar et al., 1997; Lövgren et al., 1997; Magklara et al., 2000; Meng et al., 2002; Takayama et al., 1997).

PSA was first identified and purified in the late 1970s, but widespread use in clinical urology did not occur for another decade (Ablin et al., 1970; Christensson et al., 1990; Kuriyama et al., 1980; McCormack et al., 1995; Oesterling et al., 1988; Otto et al., 1998; Seamonds et al., 1986; Sensabaugh, 1978; Stamey et al., 1987). Although ectopic expression of PSA has been reported in smaller concentrations in the tissue of malignant breast tumors (Partin et al., 2003; Yu et al., 1994a, 1994b) normal breast tissue (Christensson et al., 1990; Monne et al., 1994; Zhang et al., 2000), breast milk (Lilja et al., 1991; Végvári et al., 2010; Yu and Diamandis, 1995), and adrenal and renal carcinomas (Levesque et al., 1995; McCormack et al., 1995; Sensabaugh, 1978), **PSA is highly organ specific because it is produced primarily by prostatic luminal epithelial cells.**

The function of this androgen-regulated protease is to liquefy semen through its action on the gel-forming proteins semenogelin and fibronectin within the semen after ejaculation (Goldfarb et al., 1986; Lilja, 1985; Lilja and Weiber, 1984; McGee and Herr, 1988). In serum**, PSA circulates in bound (complexed, cPSA) and unbound forms (free, fPSA)** (Fig. 149.2). **Three proteins that are known to bind to PSA in the blood are ACT, α_2-macroglobulin (A2M), and α_1-protease inhibitor (API)** (Christensson et al., 1990; McCormack et al., 1995; Otto et al., 1998; Vieira et al., 1994). Binding of free PSA to ACT inactivates the protease, but the complex PSA-ACT remains immunodetectable (Meng et al., 2002; Partin et al., 2003).

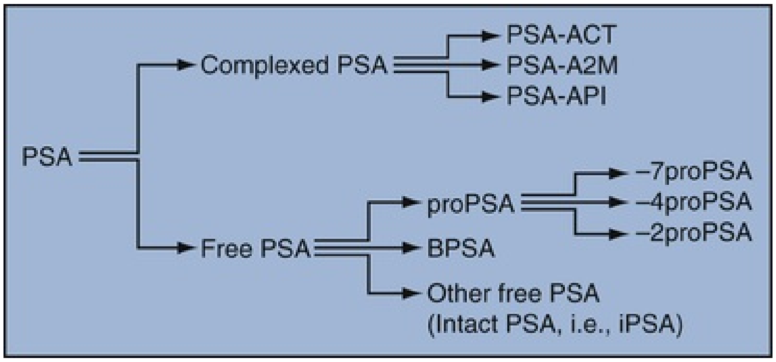

FIG. 149.2 Molecular forms of prostate-specific antigen (PSA). Molecular derivatives of PSA include free PSA, such as proPSA (and the various clipped forms), BPSA (benign PSA), and other free PSA forms such as intact, inactivated PSA. Complexed PSA includes free PSA that is bound to proteases such as ACT (α_1-antichymotrypsin), API (α_1-protease inhibitor), and A2M (α_2-macroglobulin).

The majority (approximately 70%) of PSA in serum is protein bound, most to ACT in an irreversible fashion. Only 5% to 10% of PSA is bound to A2M and 1% to 2% to API. Binding of PSA to A2M still allows some proteolytic activity but renders the PSA-A2M complex undetectable by most current assays because all PSA epitope sites become masked (Fig. 149.3) (Carter et al., 1992; Christensson et al., 1990; Oesterling et al., 1993; Zhang et al., 2000). PSA-ACT and PSA-API are detected by PSA assays, as is fPSA.

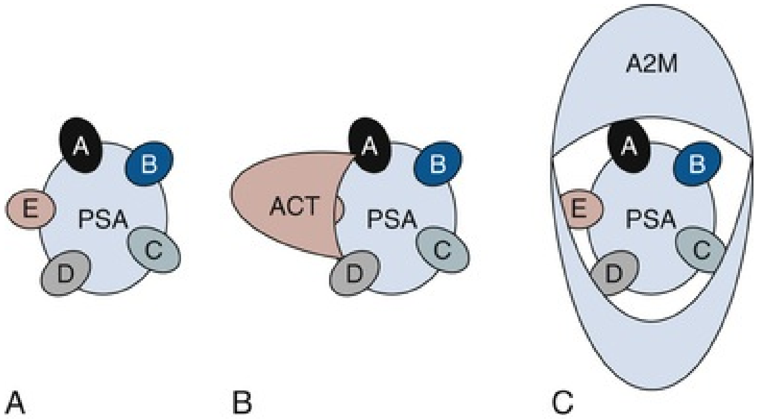

FIG. 149.3 Prostate-specific antigen (PSA)–binding proteases. (A) Free PSA with *A* to *E* representing immunoreactive epitopes of free PSA. (B) α_1-Antichymotrypsin (ACT) blocks the E epitope during binding. (C) α_2-Macroglobulin (A2M) blocks all immunoreactive sites on PSA, making this derivative difficult to measure in serum.

PSA expression is strongly androgen dependent (Henttu et al., 1992; Ohwaki et al., 2010). Immunohistochemical detection of PSA within the prostate is characterized by bimodal peaks between birth and 6 months of age and after 10 years, correlating directly with testosterone levels (Goldfarb et al., 1986; Stamey et al., 1987). Serum PSA becomes detectable at puberty with increases in luteinizing hormone and testosterone (Stamey et al., 1987; Vieira et al., 1994). **In the absence of prostate cancer, serum PSA levels vary with age, race, and prostate volume. Importantly, on a per-cell basis, PSA expression is similar**

between benign and malignant prostate cells (Armitage et al., 1988; Dalton, 1989; Meng et al., 2002; Nadler et al., 1995).

Elevated serum PSA levels are probably a product of disruption of cellular architecture within the prostate gland (Mejak et al., 2013; Stamey et al., 1987). The loss of the barrier afforded by the basal layer and basement membranes within the normal gland is a likely site for the egress of PSA into the circulation. This can occur in the setting of prostate disease (BPH, prostatitis, prostate cancer) and with prostate manipulation (prostate massage, prostate biopsy) (Ercole et al., 1987; Morote Robles et al., 1988; Stamey et al., 1987; Wang et al., 1981). Prostatic inflammation (acute and chronic) and urinary retention can cause PSA elevations to variable degrees (Armitage et al., 1988; Dalton, 1989; Etzioni et al., 2005; Marks et al., 2006; Nadler et al., 1995; Thompson et al., 2003). **Prostatic trauma, such as occurs after prostatic biopsy, can result in a temporary spike in serum PSA that persists for 4 or more weeks before returning to baseline values** (Kaplan et al., 2012; Thompson et al., 2006; Yuan et al., 1992).

Most studies of the effect of ejaculation on serum PSA have shown no significant change in PSA (Kirkali et al., 1995; McCormack et al., 1995; Woodrum et al., 1998), although in men 50 years of age and older ejaculation can lead to a very transient increase in PSA (Catalona et al., 1998; Herschman et al., 1997; Partin et al., 1998; Tchetgen et al., 1996). However, PSA appears to return to baseline within 24 hours (Rajaei et al., 2013). Men with a new PSA elevation should be asked about sexual activity within 24 hours of PSA testing and, if so, should be asked to abstain before a repeat blood draw. Long-distance cycling is another potential cause of false PSA elevation, with PSA levels increasing by approximately 10% after bicycle rides exceeding 55 kilometers (Mejak et al., 2013).

Although these factors can cause small-scale changes in PSA levels**, the presence of prostate disease (prostate cancer, BPH, and prostatitis) is certainly the most important factor affecting serum PSA** (Ercole et al., 1987; Morote Robles et al., 1988; Wang et al., 1981), **and it is primarily the impact of BPH and prostatitis on PSA levels that confounds the accuracy of PSA in the screening setting.** Prostate-directed treatment (for BPH and cancer) can lower serum PSA by decreasing the volume of prostatic epithelium available for PSA production and by decreasing the amount of PSA produced per cell. **5α-reductase inhibitors (5ARI) such as finasteride and dutasteride have been shown to lower PSA levels by roughly 50% after 12 months of treatment**

(Guess et al., 1993). **This has resulted in the so-called “doubling rule,” whereby PSA levels are multiplied by a factor of 2 in men undergoing 5ARI therapy to guide decisions regarding prostate cancer risk. However, using a multiple of 2 may overestimate PSA values in the first 6 months of treatment and underestimate PSA levels after several years of treatment** (Etzioni et al., 2005; Marks et al., 2006; Thompson et al., 2003). In addition, compelling data from the Prostate Cancer Prevention Trial (PCPT) and other sources suggest that 5ARI therapy substantially improves the performance characteristics of PSA in the screening setting with an AUC of 0.76 (finasteride) versus 0.68 (placebo) (Kaplan et al., 2012; Thompson et al., 2006). Interpretation of PSA values should always take into account the presence of prostate disease, previous diagnostic procedures, and prostate-directed treatments.

In men without BPH, the rate of change in PSA is 0.04 ng/mL per year, compared with 0.07 to 0.27 ng/mL per year in men with BPH who are between the ages of 60 and 85 years (Carter et al., 1992; Oesterling et al., 1993; Yuan et al., 1992). PSA velocity has long held interest as a potential predictor of prostate cancer in the early detection setting and as a marker of higher-risk disease in patients on active surveillance. There are now substantial data showing that PSA velocity is of minimal, if any, use for prostate cancer screening, including in patients at higher baseline risk of developing prostate cancer (Mikropoulos et al., 2018; Vickers et al., 2014). As such, **PSA velocity should not be used as a trigger for biopsy.** In the active surveillance setting, there are now more recent data that PSA kinetics can improve prediction of reclassification over time, although the clinical utility of this metric still remains to be determined (Cooperberg et al., 2018). PSA density, which is total PSA divided by prostate volume, is another PSA-derived metric and provides substantially more predictive information than PSA velocity. Proposed cutoffs for biopsy in the early detection setting have ranged from 0.08 ng/mL^2 to 0.15 ng/mL^2 (Aminsharifi et al., 2018; Nordström et al., 2018). Nordstrom et al. (2018) reported that PSA density cutoffs of 0.10 ng/mL^2 and 0.15 ng/mL^2 would lead to detection of 77% and 49% of Gleason score ≥7 tumors, respectively, in a population-based cohort with PSA of at least 3 ng/mL. **In the multicenter Prostate Cancer Active Surveillance Study, PSA density is a key predictor of adverse reclassification on surveillance biopsy** (Newcomb et al., 2016)**.**

Free Prostate-Specific Antigen

Although the majority of serum PSA is found complexed to the proteases (primarily ACT), 5% to 45% of PSA exists as enzymatically inactive fPSA (Table 149.1; McCormack et al., 1995; Woodrum et al., 1998)**. PSA produced from malignant cells appears to more frequently escape proteolytic processing, resulting in a greater fraction of serum PSA complexed to ACT and a lower percentage of total PSA that is free compared with men without prostate cancer** (Catalona et al., 1997; Christensson et al., 1993; Leinonen et al., 1993; Lilja, 1993; Stenman et al., 1994). This principle led to the development of fPSA testing as a means to improve the accuracy of PSA as a prostate cancer screening biomarker, and the FDA has approved its use in men with a serum total PSA level of 4 to 10 ng/mL and a negative DRE (Catalona et al., 1998; Partin et al., 1998).

TABLE 149.1

Molecular Derivatives of Prostate-Specific Antigen

PSA Type	% In Serum
Complexed PSA	60–95
PSA-ACT	60–90
PSA-API	1–5
PSA-A2M	10–20
Free PSA	5–45

ACT, α_1-antichymotrypsin; *API,* α_1-protease inhibitor; *A2M,* α_2-macroglobulin; *PSA,* prostate-specific antigen.

A number of studies have evaluated %fPSA cut points to determine potential thresholds that optimize the performance of this tool. Christensson et al. (1993) measured free and total PSA fractions in men with and without prostate cancer and found that a free/total PSA cutoff of 0.18 (18% fPSA) significantly improved the ability to distinguish between subjects with and without cancer compared with use of total PSA alone. As many as 20% to 65% of unnecessary biopsies may be avoided when using %fPSA cutoff values ranging between 14% and 28% while maintaining sensitivity rates from 70% to 95% within the tPSA range of 4 to 10 ng/mL (Catalona et al., 1998; Partin et al., 1998; Polascik et al., 1999; Pound et al., 1997; 1999; Stephenson and Stanford, 1997; Veltri and Miller, 1999; Vessella et al., 2000). In a prospective, multi-institutional study of men aged 50 to 75 years with PSA levels between 4 and 10 ng/mL and palpably benign prostate glands, a %fPSA cutoff of 25% detected 95% of cancers (sensitivity) while avoiding 20% of unnecessary biopsies (specificity) (Catalona et al., 1998; Gretzer et al., 2002). This resulted in an AUC for %fPSA that was significantly higher than that of total PSA (0.72 vs. 0.53).

Although there remains no single, established %fPSA threshold, proposed cut points generally range from 15% to 25%. The National Comprehensive Cancer Network Prostate Cancer Early Detection Guidelines incorporate %fPSA as an option to help with decision making before biopsy and recommend a threshold of 10% (Carroll and Mohler, 2018). However, an important recent development has been the increasing availability and usage of predictive tools that incorporate multiple clinical variables such as total PSA, %fPSA, and DRE findings (Hernandez et al., 2009; Pepe et al., 2001; Zaytoun et al., 2011). **In particular, the updated calculator based on results of the prostate cancer prevention trial (PCPT) provide a calibrated estimate of prostate cancer risk that can facilitate shared clinical decision making (Fig. 149.4;** Andriole et al., 2009; Ankerst et al., 2012; Schröder et al., 2009). fPSA decreases in a similar fashion as total PSA in the setting of 5ARI therapy; thus the percentage of fPSA is not altered significantly by these medications (Keetch et al., 1997; Pannek et al., 1998).

Ankerst DP, Hoefler J, Bock S, Goodman PJ, Vickers A, Hernandez J, Sokoll LJ, Sanda MG, Wei JT, Leach RJ, Thompson IM. The Prostate Cancer Prevention Trial Risk Calculator 2.0 for the prediction of low- versus high-grade prostate cancer. Urology, 2014, to appear.

Based on the provided risk factors a prostate biopsy performed would have a:

4% chance of high-grade prostate cancer,

10% chance of low-grade cancer,

86% chance that the biopsy is negative for cancer.

About 2 to 4% of men undergoing biopsy will have an infection that may require hospitalization.

Please consult your physician concerning these results.

FIG. 149.4 Web-based calculation of prostate-cancer risk using the PCPT risk calculator operationalized by the University of Texas Health Science Center at San Antonio (**http://deb.uthscsa.edu/UROR iskCalc/Pages/calcs.jsp**). Distinct nomograms using different patient factors and biomarkers are available, and the output for the most commonly used nomograms gives the risk of high-risk cancer and any prostate cancer using a pictorial interface.

In addition to contributing to detection, fPSA may provide prognostic information. Serial measurement of %fPSA within archival serum has shown significant differences in aggressive and nonaggressive prostate cancers (Carter et al., 1997). This study suggested that the longitudinal measurement of %fPSA changes may not only aid in detection but also contribute information regarding disease behavior. A number of studies have reported on the correlation between

%fPSA and pathological outcomes, showing some correlation between low %fPSA and aggressive pathological features (Aus et al., 2003; Masieri et al., 2012; Morote et al., 2000; Shariat et al., 2006). In addition, Shariat et al. (2006) reported an independent association between lower %fPSA and biochemical recurrence in 402 men who underwent radical prostatectomy for clinically localized disease.

Perhaps the clinical setting in which %fPSA is most often used is in patients with an elevated PSA and a prior negative prostate biopsy (Djavan et al., 2000; Hayek et al., 1999; Stephan et al., 1997). Stephan et al. (1997) reported a 5% cancer underdiagnosis rate when using a %fPSA value of 21% to trigger rebiopsy, and Catalona et al. (1997) reported that a threshold of 28% detected 95% of cancers and avoided 12% of repeat biopsies. More recent European data reported an AUC of 0.73 for %fPSA in a repeat biopsy population, exceeding that of PSA and PCA3 (Auprich et al., 2012). At a threshold of 18%, %fPSA demonstrated a sensitivity of 85% and specificity of 41%. However, the AUC for %fPSA was only 0.52 in another European repeat biopsy cohort, suggesting a need for other biomarkers in this setting (Scattoni et al., 2013).

Free Prostate-Specific Antigen Isoforms

fPSA in serum comprises three isoforms: proPSA, BPH-associated PSA (BPSA), and intact fPSA (Jansen et al., 2009; Mikolajczyk et al., 2002). These three isoforms exist in approximately equal concentrations in serum, and each has shown promise as a prostate cancer biomarker. As discussed earlier, PSA originates with a 17–amino acid chain that is cleaved to yield a precursor inactive form of PSA termed proPSA (Kumar et al., 1997; Mikolajczyk et al., 1997, 2000, 2001; Peter et al., 2001; Zhang et al., 1995). As depicted in Fig. 149.5, **the precursor form of PSA contains a 7–amino acid proleader peptide, in addition to the 237 constituent amino acids of mature PSA, and is termed proPSA or [−7]proPSA.** This leader amino acid chain is cleaved by hK2, resulting in the active form of PSA. Incomplete removal of the 7–amino acid leader chain has led to the identification of various other truncated or clipped forms of proPSA. These include proPSAs with 2–, 4–, and 5–leader amino acids ([–2]pPSA, [–4]pPSA, and [–5]pPSA), and all are primarily expressed in the peripheral zone of the prostate. **With cellular disruption, these enzymatically inactive forms circulate as fPSA and may constitute the majority of the circulating fPSA in patients with prostate cancer** (Mikolajczyk et al., 1997; Fig. 149.6).

FIG. 149.5 Differential cleavage and activation of pro–prostate-specific antigen (PSA). ProPSA is released from the prostate epithelial cell with a 7–amino acid leader sequence. hK2 cleaves the amino acid leader to activate PSA. Active PSA undergoes proteolysis to yield inactive PSA (iPSA) and may also undergo internal degradation to form benign PSA (BPSA). Partial cleavage of the 7–amino acid leader sequence yields inactive forms of proPSA (i.e., [–2]pPSA or [–4]pPSA).

FIG. 149.6 Prostate-specific antigen (PSA) synthesis in normal versus cancer tissue. ProPSA is secreted into the lumen, where the 7–amino acid leader sequence is cleaved by hK2 to yield active PSA. Some of the active PSA diffuses into the serum, where it is bound to proteases such as α_1-antichymotrypsin (ACT). The luminal active PSA undergoes proteolysis, and the resulting inactive PSA (iPSA) may also enter the circulation to circulate in the unbound or free state. In prostate cancer, loss of the tissue

architecture may permit a relative increase in bound PSA and proPSA in serum.

Reports by Mikolajczyk et al. (2000, 2001) have revealed significantly elevated levels of these truncated forms of proPSA in prostate cancer tissue. In particular, the [−2]proPSA isoform, cleaved between leucine 5 and serine 6 of the propeptide, has shown increasing promise as a serum prostate cancer biomarker (Lazzeri et al., 2012; 2013; Le et al., 2010). Although the underlying biology behind the increased levels of [−2]proPSA in prostate cancer remains unclear, it may be that the decreased PSA processing in prostate cancer results in a relative increase in proPSA and its cleaved forms, especially [–2]proPSA. In addition, Makarov et al. (2009) have proposed that proPSA production may be driven by benign tissue adjacent to malignant prostatic epithelium.

From a clinical standpoint, [−2]proPSA has been extensively validated in the screening setting, before either initial biopsy or repeat biopsy (Guazzoni et al., 2011; Lazzeri et al., 2012, 2013; Le et al., 2010; Loeb et al., 2015, 2017). Lazzeri et al. (2013) reported on a prospective European cohort of 646 patients with total PSA between 2 and 10 ng/mL who were undergoing initial prostate biopsy. The %[−2]proPSA was a strong independent predictor of prostate cancer at biopsy in a model that included free and total PSA, and the AUC for %[−2]proPSA was 0.67. The %[−2]proPSA was also a strong predictor of Gleason score ≥7 prostate cancer in this study. In the United States, a prospective National Cancer Institute (NCI) EDRN validation study demonstrated excellent performance characteristics for %[−2]proPSA (Sokoll et al., 2010). Including %[−2]proPSA in the base model consisting of free and total PSA significantly improved the predictive accuracy, and %[−2]PSA outperformed PSA and %fPSA in predicting the presence of prostate cancer at the time of biopsy in patients with a serum total PSA of 2 to 10 ng/mL. In addition, %[−2]proPSA was closely correlated with increasing Gleason score.

The levels of [−2]proPSA have been incorporated into a formula that also includes free and total PSA and is called the Prostate Health Index (PHI) (Lazzeri et al., 2013). PHI is FDA approved in men aged 50 years and older with total PSA 4 to 10 ng/mL and negative DRE. The accuracy of PHI for predicting clinically significant prostate cancer in the early detection setting is consistently better than PSA or %fPSA, and adding PHI to existing risk calculators such as PCPT significantly improves their performance (Loeb et al., 2015, 2017; Tosoian et al., 2017). PHI is also strongly associated with reclassification in men on active surveillance (Hirama et al., 2014; Tosoian et al., 2012). This test is discussed in more detail in Chapter 152.

Another isoform of fPSA, referred to as benign PSA or BPSA, is identical to mature PSA except for internal cleavages between Lys 182 and Lys 145 (Mikolajczyk et al., 2002). Its expression is generally limited to transition zone tissue, and it is highly expressed in the setting of BPH (Canto et al., 2004; Mikolajczyk et al., 2000; Wang et al., 2000). BPSA is closely related to prostate volume and does not appear to have any prognostic capacity in terms of distinguishing potentially indolent from aggressive disease (de Vries et al., 2005; Naya et al., 2004). Although serum BPSA alone is unlikely to differentiate between hyperplasia and cancer, in combination with assays for [−2]proPSA, it may allow additional discrimination (Rhodes et al., 2012; Stephan et al., 2009).

So-called “intact PSA” comprises an additional fPSA subset that has been identified as a predictive serum biomarker (Hori et al., 2013; Nurmikko et al., 2000; Steuber et al., 2007a). Preliminary studies have demonstrated that the ratio of intact to free PSA may improve the accuracy of prostate cancer detection (Nurmikko et al., 2000, 2001; Steuber et al., 2002). However, some studies of intact PSA include proPSA in their intact PSA assay, making it difficult to determine the predictive value of intact PSA alone (Peltola et al., 2011). This parameter has primarily been used as part of a multi-kallikrein panel, which is discussed later in this chapter (Vickers et al., 2008).

Prostate-Specific Membrane Antigen

The glycoprotein prostate-specific membrane antigen (PSMA) has been evaluated for a number of years as a potential serum, urine, and/or tissue biomarker of prostate cancer. A folate hydrolase, PSMA is found embedded within the cell membrane of all prostatic epithelial cells. It is a type II transmembrane protein with an extracellular C-terminus that exists as a dimer and binds glutamate and glutamate-like structures (Fair et al., 1997; Israeli et al., 1997). The gene for PSMA has been cloned, fully sequenced, and localized to the short arm of chromosome 11 (11p11-p12). Although PSMA is predominantly expressed in the secretory acinar epithelium of the prostate gland, it has been isolated in other tissues, including in the central nervous system (astrocytes and Schwann cells) and intestine (jejunal brush border).

Of interest for diagnosis (Douglas et al., 1997), prognosis (Perner et al., 2007), and imaging (Ristau et al., 2013) is the discovery of elevated expression of this protein in tissue from prostate cancer compared with normal prostate tissue

(Chang et al., 1999; Elgamal et al., 2000; Minner et al., 2011; Silver et al., 1997). There is also evidence that increased tissue expression of PSMA may confer a worse prognosis in patients undergoing radical prostatectomy (Minner et al., 2011; Perner et al., 2007).

Currently, PSMA has its greatest use in targeted imaging and theranostics (Barrett et al., 2013; Milowsky et al., 2007; Osborne et al., 2013; Tagawa et al., 2013). In particular, ^{68}Gallium prostate-specific membrane antigen positron emission tomography (^{68}Ga-PSMA PET) has become an increasingly used diagnostic tool in the setting of biochemical recurrence after primary therapy. A meta-analysis of 15 studies found 69% of patients with detectable disease, leading to increases in use of radiotherapy and salvage lymphadenectomy along with concomitant decreased use of systemic therapy (Han et al., 2018). Another meta-analysis reported 40% of patients with positive ^{68}Ga-PSMA PET scans at the time of primary staging and 76% positive at the time of biochemical recurrence (Perera et al., 2016). Specificity of this modality approaches 97%, and even at PSA levels as low as 0 to 0.2, 42% of patients in this report were found to have positive scans.

Human Kallikrein 2

Human kallikrein peptidase 2 (hK2) shares many important properties with PSA and has demonstrated potential as another prostate cancer tumor marker (Becker et al., 2000; Darson et al., 1997; Kumar et al., 1997; Lövgren et al., 1999; Rittenhouse et al., 1998; Young et al., 1992). **Among many similarities, hK2 and PSA share 80% amino acid homology** (see Fig. 149.1)**, exhibit similar specificity for prostate tissue, and are hormonally regulated by androgens.** As discussed earlier, one of the key functions of hK2 is to activate the zymogen (proPSA) to the active PSA through cleavage of the amino acid presequence (see Fig. 149.6).

Critical to its utility as a biomarker, hK2 expression varies independent of PSA expression, in tissue and serum (Tremblay et al., 1997). For example, **in benign epithelium, PSA is intensely expressed compared with minimal immunoreactivity of hK2** (Darson et al., 1999; Tremblay et al., 1997)**. In contrast, in cancerous tissue hK2 is expressed more intensely.** Furthermore, tissue expression of hK2 appears to correlate with more aggressive pathological features, including Gleason grade (Darson et al., 1997, 1999; Tremblay et al., 1997).

A number of studies have shown an association between serum hK2 levels and the presence of prostate cancer, suggesting that it may be used in conjunction with PSA to improve the selection of patients for prostate needle biopsy (Becker et al., 2000; Nam et al., 2000; Vickers et al., 2007). Furthermore, men with low-grade disease have lower concentrations of serum hK2 than men with more aggressive cancer (Darson et al., 1999). Data from a multicenter study demonstrated a statistically significant difference between men with biopsies positive for cancer, looking at hK2 alone and in combination with fPSA/tPSA (Kwiatkowski et al., 1998). Combining fPSA and hK2, Partin et al. (1999) demonstrated an increased cancer detection rate within the tPSA range of 2 to 10 ng/mL. Serum hK2 may also offer prognostic information: studies show correlations with aggressive pathological features as well as biochemical recurrence (Haese et al., 2001; Steuber et al., 2007b).

Currently, hK2 used clinically as one of the components of the 4Kscore, a multi-kallikrein panel reported by Vickers et al. (2008). Early reports used a large cohort of men from the Goteborg arm of the European Randomized Study of Screening for Prostate Cancer (ERSPC) to combine, within a statistical model, four kallikrein forms (total PSA, fPSA, intact PSA, and hK2) to accurately predict the presence of prostate cancer in men with a PSA of at least 3.0 ng/mL (AUC 0.84). These findings were then validated in a separate ERSPC cohort (Rotterdam arm) in which it was suggested that use of the multi-kallikrein panel could avoid 513/1000 biopsies with only 54/177 missed low-grade cancers and 12/100 missed high-grade cancers (Vickers et al., 2010). In addition, of 392 men in this arm who underwent radical prostatectomy between 1994 and 2004, the four kallikrein markers were independently associated with pathologically aggressive disease features and improved the accuracy of the base model (AUC 0.81 to 0.84) (Carlsson et al., 2013).

Although the statistical model has not been the same in all studies, there have been multiple studies validating the performance of this assay. In a US-based study of 1012 men undergoing prostate biopsy, the 4Kscore would decrease biopsy rates by 30% to 58% while missing 1.3% to 4.7% of Gleason score ≥7 tumors, depending on the threshold used (Parekh et al., 2013). A meta-analysis using individual patient data has demonstrated the value of all four components of the kallikrein panel, and this same data analyzed across multiple different patient subgroups showed a mean increase in AUC of 0.11 when the 4Kscore was added to a base clinical model (Vickers et al., 2018a,b).

Circulating Tumor Cells and Circulating Tumor DNA

Circulating tumor cells (CTCs) have long been touted as potential prognostic biomarkers and treatment response indicators. The excitement in this area of research goes back more than 20 years, when investigators demonstrated the ability to detect PSA mRNA in the blood of men with advanced prostate cancer (Katz et al., 1994). Subsequent CTC research in prostate cancer has used a wide range of methods, capitalizing on features such as size, surface marker expression, and cellular plasticity that differentiate CTCs from circulating mononuclear cells in the blood (Danila et al., 2011; Pantel and Alix-Panabières, 2010; Yu et al., 2011). Typically, CTCs are defined as being $CD45^-$ and positive for an epithelial marker such as epithelial cell adhesion molecule (EpCAM) and/or cytokeratin. Although the development of CTCs as a prostate cancer biomarker has been relatively slow to evolve, there has been substantial recent progress in this field with a movement toward an increasing number of clinical assays.

Currently, there is only one FDA-approved methodology for identifying CTCs: CellSearch (Veridex, Warren, NJ). The CellSearch system uses antibodies against EpCAM for CTC capture and then stains with antibodies against CD45 (negative) and cytokeratins 8, 18, and 19 (positive) to identify individual CTCs. With this system, a CTC count of 5 or more cells per 7.5 mL of blood at any time during the course of the disease has been associated with a poor prognosis in prostate, breast, and colorectal cancers (Cohen et al., 2008; Cristofanilli et al., 2004; de Bono et al., 2008; Shaffer et al., 2007). In a study of 422 patients with metastatic prostate cancer, using the CellSearch platform the investigators demonstrated that there was a difference between baseline numbers of cells and those seen 2 to 5 weeks post-treatment (Fig. 149.7). For example, 57% of the patients had greater than 5 cells per 7.5 mL of blood before treatment, and 39% had greater than 5 cells per 7.5 mL after treatment (Shaffer et al., 2007). Similar studies have lent further support to the potential use of CTCs as a response indicator, with conversion from unfavorable to favorable CTC counts (<5 CTCs) frequently occurring in men with advanced prostate cancer receiving hormonal agents or chemotherapy (Danila et al., 2010; de Bono et al., 2008; Reid et al., 2010). Further data demonstrating that CTC response independently predicts survival in these settings are needed before CTCs can be used as an efficacy-response surrogate marker (Scher et al., 2009, 2013).

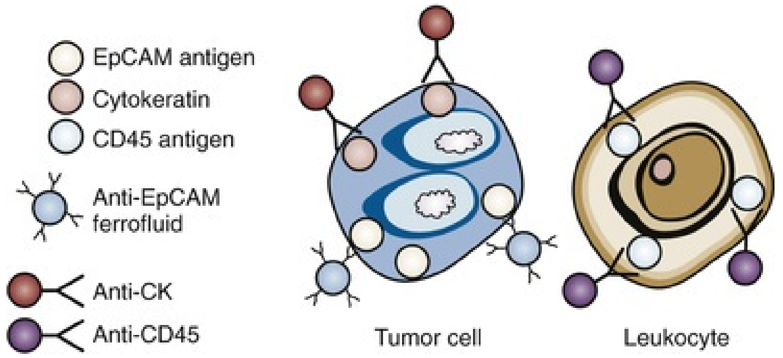

FIG. 149.7 CellSearch CTC: Circulating Tumor Cell (Veridex) cell enumeration system. *CD45,* CD stands for "*cluster of differentiation,*" which was originally called *leukocyte common antigen; CK,* cytokeratin; *EpCAM,* epithelial cell adhesion molecule. The anti-EpCAM ferrofluid captures the cells, and they are then validated with cytokeratin-positive and CD45-negative staining.

A number of other platforms for CTC detection have been developed, and this continues to be an area of rapid growth in the biomarker space. Investigators at Harvard Medical School developed a microfluidic system known as the "CTC-Chip," which has garnered a great deal of attention (Nagrath et al., 2007). This system has a high level of sensitivity, able to detect a single EpCAM-positive cell among 1 billion blood cells, and the capture efficiency has been further improved with an updated device (Nagrath et al., 2007; Stott et al., 2010).

Going forward, the use of CTCs as a biomarker will likely revolve less around simple enumeration and more around the specific molecular alterations that can be identified—either within the cells or from cell-free nucleic acids—providing a real-time "liquid biopsy" in men with prostate cancer (Danila et al., 2011, 2014; Dawson et al., 2013). **In 2014 a seminal study published in the *New England Journal of Medicine* demonstrated that detection of the androgen-receptor splice variant 7 (AR-V7) in CTCs predicts resistance to abiraterone and enzalutamide in metastatic castration-resistant prostate cancer** (Antonarakis et al., 2014). These results were subsequently validated in a larger study, which also demonstrated that outcomes were best for patients without CTCs, intermediate for patients with AR-V7–negative CTCs, and worst for patients with AR-V7–positive CTCs (Antonarakis et al., 2017). **Similar findings were demonstrated using another commercially available platform based on digital imaging, which found that patients with nuclear expression of AR-V7 in CTCs responded better to taxane therapy than abiraterone or enzalutamide** (Scher et al., 2016).

Instead of capturing cells in circulation to evaluate gene expression, cell-free

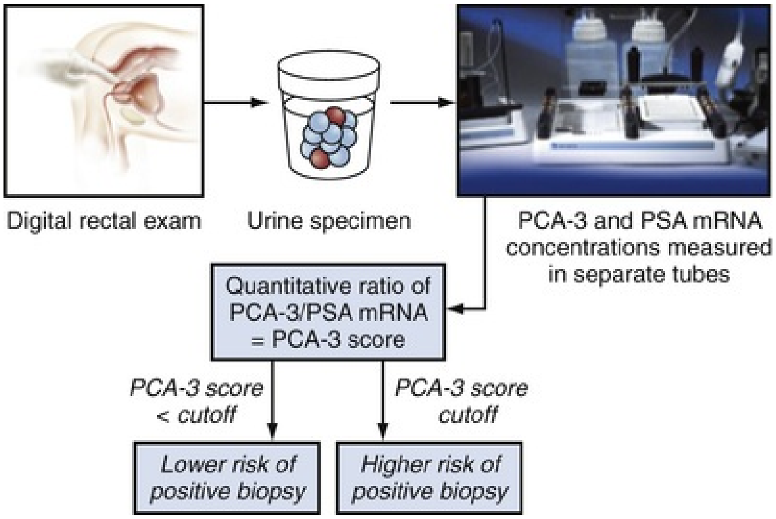
DNA can be analyzed to detect and characterize circulating tumor DNA (ctDNA). The goal of these approaches is generally to profile a tumor's somatic alterations, which can then potentially be used for early detection or to inform prognosis and/or treatment in patients with known cancer. For example, the recently described CancerSEEK test combines ctDNA analysis with additional circulating markers in a single early detection assay covering multiple cancer types (Cohen et al., 2018). In advanced disease, ctDNA can inform the timing and mechanism of therapeutic resistance and potentially be used to guide subsequent treatment decisions (Goodall et al., 2017).

Urine-Based Biomarkers

PCA3

Given the ease of collecting urine specimens and the known shedding of prostate cells, urine has long held promise as a potential biomarker source in prostate cancer (Truong et al., 2013). It was not until relatively recently, however, that urinary biomarkers of prostate cancer have come into clinical use. The first of these, prostate cancer antigen 3 (PCA3), was initially described by Bussemakers et al. (1999), who used differential display and Northern blot analysis to compare normal and prostate cancer tissue. They were able to identify a prostate cancer–specific gene on chromosome 9q21-22 that, although it does not encode a protein, is one of the most sensitive and specific prostate cancer biomarkers. Although its function remains unknown, multiple studies have demonstrated that PCA3 is a long noncoding RNA (lncRNA) that is not expressed outside of the prostate, and PCA3 levels in malignant tissue generally far exceed levels in benign tissue (de Kok et al., 2002; Popa et al., 2007). **Early studies used reverse transcription polymerase chain reaction (RT-PCR) assays to detect PCA3 in urine and showed improved performance characteristics for PCA3 over PSA in diagnosing prostate cancer** (Hessels et al., 2003; van Gils et al., 2007).

More recently, a transcription-mediated amplification assay was developed, offering improved sensitivity and quantitation relative to standard RT-PCR (Groskopf et al., 2006). **This has become the commercial assay (Progensa, Hologic Inc.), which is CE marked and FDA approved (2012) to assist with decisions in the setting of a prior negative prostate needle biopsy.** To enhance the sensitivity of PCA3 detection, urine samples are collected after an “attentive” digital rectal examination (Fig. 149.8). This involves three firm strokes on each lobe of the prostate toward the median sulcus, and the first 20 to 30 mL of voided urine should be collected within 1 hour (Sokoll et al., 2008). The commercial PCA3 score is reported as the ratio of urine PCA3 mRNA/urine PSA mRNA × 1,000, thus normalizing PCA3 expression to PSA expression.



Digital rectal exam
Urine specimen
PCA-3 and PSA mRNA concentrations measured in separate tubes
Quantitative ratio of PCA-3/PSA mRNA = PCA-3 score
PCA-3 score < cutoff
PCA-3 score cutoff
Lower risk of positive biopsy
Higher risk of positive biopsy

FIG. 149.8 PCA3 assay protocol. After "attentive" digital rectal exam, urine is collected. RT-PCR determines the mRNA levels for PCA3 and PSA. The ratio between PCA3/PSA determines the PCA3 score. Prostate cancer risk level suggests need for biopsy. (From Groskopf J, Aubin SM, Deras IL, et al.: APTIMA PCA3 molecular urine test: development of a method to aid in the diagnosis of prostate cancer. *Clin Chem* 52:1089–1095, 2006.)

Numerous clinical studies have now been performed to evaluate the utility of urine PCA3 to serve as a prostate cancer biomarker, and all have shown that PCA3 scores are closely correlated with the likelihood of a positive biopsy (Alshalalfa et al., 2017; Deras et al., 2008; Hessels et al., 2003; Roobol et al., 2010b; van Gils et al., 2008). Deras et al. (2008) reported that men with a PCA3 below 5 had a 14% positive biopsy rate, compared with a 70% positive biopsy rate in men with PCA3 above 100. However, in another study, patients with PCA3 above 100 had only a 52% positive biopsy rate (Roobol et al., 2010a). Unlike PSA, PCA3 levels are independent of prostate size (Haese et al., 2008).

One of the critical challenges in using PCA3—or any biomarker reported as a continuous score rather than just "positive/negative"—is establishing appropriate cutoffs. Given that PCA3 scores represent a continuum of risk, different thresholds will lead to differences in sensitivity and specificity of the assay. Multiple cutoffs have been proposed, most commonly 10, 25, and 35 (Crawford et al., 2012; Haese et al., 2008). Haese et al. (2008) reported on a cutoff of 35, with positive biopsies in 39% of those above versus 22% in those below the threshold. In a comparative effectiveness review commissioned by the US Agency for Healthcare Quality and Research, Bradley et al. (2013) showed that a threshold of 25 results in a sensitivity of 74% and specificity of 57% (false-positive rate of 43%). **It is this lower threshold of 25 that was used in the**

FDA approval. However, different thresholds may be required for different patient populations of clinical scenarios. For example, using a PCA3 score of less than 20 in men with repeat prostate biopsy, Wei et al. (2014) reported a negative predictive value of 88%, and a sensitivity and specificity of 76% and 52%, respectively. However, in men being seen for an initial prostate biopsy using a PCA3 score of more than 60, Wei et al. reported a positive predictive value of 80% and a sensitivity and specificity of 42% and 91%, respectively (Wei et al., 2014).

There are increasing reports on the use of PCA3 in the initial screening setting of patients without a prior biopsy. Roobol et al. (2010b) reported on a cohort of 721 men, the majority of whom had not previously undergone a biopsy and showed that PCA3 (AUC 0.64) outperformed PSA (AUC 0.58) in predicting cancer on subsequent biopsy. In a prospective, community-based evaluation of PCA3 in 1962 men before any prostate biopsy, prostate cancer was detected in 61% of men with a PCA3 of at least 35 and 32% with a PCA3 below 35 (Crawford et al., 2012). The AUC for PCA3 was 0.71 compared with an AUC of 0.57 for PSA. Another study of 3073 men undergoing initial biopsy demonstrated that PCA3 was an independent predictor of any prostate cancer and high-grade prostate cancer after controlling for additional clinical variables (Chevli et al., 2014). Although PCA3 performed better than PSA for the detection of any cancer (AUC 0.70 vs. 0.60), they performed similarly for the detection of high-grade cancer (AUC 0.68 vs. 0.68).

To improve the predictive accuracy of PCA3, a number of nomograms have been developed that incorporate PCA3 along with other known clinical predictors to identify men most likely to have a positive prostate biopsy. For example, Chun et al. (2009) showed that PCA3 improves the accuracy of a base clinical model (AUC 0.73 vs. 0.68) and proposed a final model that incorporated a PCA3 cutoff of 17. Similarly, Ankerst et al. (2008) reported on an updated version of the Prostate Cancer Prevention Trial (PCPT) nomogram that includes PCA3 as a continuous variable. The final model outperformed the base PCPT model (0.70 vs. 0.65) and has been operationalized on the web (as in Fig. 149.4). Another nomogram incorporating PCA3 and clinical variables was developed by Elshafei et al. (2015) for predicting prostate cancer and high-grade prostate cancer in an initial biopsy setting with C-indices of 0.74 and 0.77, respectively, compared with 0.70 and 0.75, respectively, without PCA3. Given the available data, the comparative effectiveness review by Bradley et al. (2013) concluded that PCA3 appears to be superior to total PSA in diagnosing prostate cancer, but that further evidence is needed and there is not yet evidence that use of PCA3 leads to better health outcomes.

Gene Fusions

With the landmark discovery of the presence of gene fusions in prostate cancer by Tomlins et al. (2005), considerable work has been performed to determine their potential utility as prostate cancer biomarkers. **In particular, fusions of the 5′untranslated region of the androgen-regulated gene transmembrane protease, serine 2 (TMPRSS2) with v-ets erythroblastosis virus E26 oncogene homolog (ERG) or ets variant 1 (ETV1) were found to be nearly 100% specific for prostate cancer and present in at least 50% of PSA-screened prostate cancers. ERG and ETV1 are members of the erythroblastosis virus E26 transformation-specific (ETS) transcription factor family, and TMPRSS2:ERG fusions represent about 90% of all ETS gene fusions** (Tomlins et al., 2009; Young et al., 2012).

Although tissue-based detection of the fusion using either chromosomal analysis (i.e., fluorescence in situ hybridization) or immunohistochemical staining for ERG has shown some utility, this biomarker appears to have its greatest potential as a urine-based assay (Hessels et al., 2007; Laxman et al., 2006, 2008). A feasibility study that examined urine samples post-DRE confirmed that the *TMPRSS2:ERG* fusion can indeed be detected in the urine and may aid in the decision to proceed with a prostate biopsy (Laxman et al., 2008). Like PCA3, TMPRSSS2:ERG levels are normalized to urine PSA mRNA expression. Tomlins et al. (2011) reported on the development and use of a clinical grade assay based on transcription-mediated amplification (similar to the PCA3 assay) in 1312 men before prostate biopsy. TMPRSS2:ERG outperformed serum PSA for predicting the presence of prostate cancer with an AUC of 0.65 to 0.71 versus 0.59 to 0.61. In addition, in a subset of men who underwent prostatectomy, higher urine TMPRSS2:ERG score was associated with increased tumor volume, higher-grade disease, and non–organ-confined cancer.

Moving toward the concept that single biomarkers will probably not answer the important clinical questions in prostate cancer alone, many investigators have begun to multiplex markers, resulting in additive value. Specifically, given that TMPRSS2:ERG is found in only half of all prostate cancer foci (approximately 75% of men with cancer), its greatest utility will be in combination with other biomarkers. It has been evaluated closely in concert with

PCA3, and the two biomarkers together appear to provide improved performance over either one alone (Hessels et al., 2007; Laxman et al., 2008; Salami et al., 2013; Tomlins et al., 2016). In the 1312 patient cohort reported by Tomlins et al. (2011), combining TMPRSS2:ERG and PCA3 scores with the PCPT nomogram resulted in an AUC for predicting cancer of 075 to 0.79. TMPRSS2:ERG + PCA3 score groups were also shown to correlate with features of disease aggressiveness such as Gleason grade, although data in this area continue to be mixed (Gopalan et al., 2009; Leyten et al., 2014).

Three other large studies have reported on the combination of TMPRSS2:ERG and PCA3 for predicting the presence of prostate cancer (Sanda et al., 2017). Cornu et al. (2013) showed that PCA3 and TMPRSS2:ERG were independent predictors of prostate cancer in a multivariable model that also included other clinical parameters. Leyten et al. (2014) reported on the prospective use of the combined assay in 497 patients at 6 centers in Europe. The combination of PCA3 and TMPRSS2:ERG increased the performance of the European Randomized Study of Screening for Prostate Cancer (ERSPC) risk calculator from an AUC of 0.80 to 0.84. In addition, the sensitivity of PCA3 increased from 68% to 76% when TMPRSS2:ERG was added. More recently, Sanda et al. (2017) reported that combined testing of urinary T2:ERG and PCA3 at thresholds that preserved 95% sensitivity for detecting aggressive prostate cancer improved specificity from 18% to 39% in the training cohort and from 17% to 33% in the validation cohort. Further, 42% of unnecessary prostate biopsies would have been avoided using the combined urine assay, with the greatest potential benefit in younger men. Currently, the combined test is commercially available as The Mi-Prostate Score (MiPS, University of Michigan Health System), combining serum PSA, urine PCA3, and urine TMPRSS2:ERG to provide a quantitative risk estimate of the likelihood of detecting prostate cancer on prostate biopsy as well as the probability of detecting high-grade cancer (Tomlins et al., 2016). This test may also have a role in the management of patients on active surveillance for prostate cancer, because it has been correlated with features of tumor aggressiveness in a prospective active surveillance cohort (Lin et al., 2013).

Other Urine Biomarkers

Recently, Van Neste et al. (2016) reported that HOXC6 and DLX1 mRNA levels in urine in combination with clinical factors improved the detection of high-grade prostate cancer with overall AUC of 0.86 and 0.90 in the training and validation cohorts, respectively. The authors performed a decision curve analysis, which revealed a strong net benefit with the best reduction in unnecessary biopsies compared with other clinical decision-making tools, such as the PCPT risk calculator and the PCA3 assay. This assay is now commercially available as the SelectMDx test.

Annexin A3

Another potential urine-based prostate cancer biomarker is annexin A3, which is inversely related to the presence of prostate cancer. This protein is part of a family of calcium and phospholipid binding proteins that have been shown to be altered in cancer (Köllermann et al., 2008; Wozny et al., 2007). Evaluating annexin A3 concentrations in post-DRE urine before prostate needle biopsy, Schostak et al. (2009) evaluated the potential clinical utility of urine-based annexin A3, either as a stand-alone biomarker or together with PSA. In a blinded study that consisted of training and evaluation sets of 243 and 264 men, respectively, these investigators showed that annexin A3 added to the ability of PSA to predict a positive needle biopsy with a combined AUC of 0.81. Using a multiplex approach, Cao et al. (2011) reported on the combination of urine annexin A3, PCA3, TMPRSS2:ERG, and sarcosine to help identify patients with prostate cancer. The multi-marker model demonstrated a high level of predictive accuracy with an AUC of 0.84 in patients with PSA 4 to 10 ng/mL and an AUC of 0.86 across all patients in their cohort.

miRNA

Based upon the realization that a majority of the DNA in the genome does not encode protein sequences, the utility of these sequences in the regulation of gene expression has been under intense investigation. Among the most important components of this regulation are microRNAs (miRNAs). These are small (approximately 19–22 nucleotide) noncoding, single-strand RNAs involved in the regulation of mRNA. They have been detected in a wide range of biologic fluid and are being explored as potential biomarkers in across a variety of malignancies. Given their potential mechanistic role, they may provide diagnostic and prognostic information. In prostate cancer, miR-141 has shown promise in a number of studies in terms of its association not only with prostate cancer but potentially also with disease aggressiveness (Bryant et al., 2012;

Mitchell et al., 2008). In addition, Casanovas-Salas et al. (2014) recently reported that urine miR-187 is an independent predictor of prostate cancer at needle biopsy. Although these findings must be expanded to larger populations of individuals, this remains a promising family of potential markers.

Tissue-Based Biomarkers

α-Methylacyl Coenzyme A Racemase

α-methylacyl coenzyme A racemase *(AMACR)* gene, located on chromosome 5, is upregulated in prostate cancer tissues (Luo et al., 2002; Rubin et al., 2002). *AMACR* functions as an enzyme responsible for the beta-oxidation of branched-chain fatty acids obtained in diets consisting of beef and dairy products. Luo et al. (2002) demonstrated that 88% of prostate cancer cases and untreated metastasis and hormone-refractory prostate cancers were strongly positive for *AMACR*. Immunohistochemical studies by Rubin et al. (2002) have shown that *AMACR* expression in biopsy tissue may provide 97% sensitivity and 100% specificity for prostate cancer detection. Furthermore, in combination with other markers, such as TP63, that aid in identifying basal cells absent in prostate cancer, measurement of *AMACR* has potential for the development of molecular probes to aid in the detection of prostate cancer. As a result, *AMACR* immunostaining is sometimes performed on prostate needle biopsies to confirm the presence of cancer. *AMACR* may also have some prognostic utility: decreased staining levels are associated with an increased risk of disease progression (Rubin et al., 2005). Although other roles for *AMACR* as a biomarker have shown some promise—for example, as a urinary assay for prostate cancer detection—the performance of serum and urine tests has not been sufficient to warrant clinical use to date.

Epigenetic Modifications

Changes in gene expression may occur as a result of alterations in DNA, and epigenetic changes are those not caused by alterations in DNA sequence. These epigenetic modifications include changes in DNA methylation and histone acetylation status. Segments within the gene promoter that are composed of GC-rich regions are termed CpG islands. **Alterations in the methylation status of these regions may affect gene expression and have been shown to play a role in carcinogenesis** (Jones and Baylin, 2002). Furthermore, cumulative effects of environmental exposures, such as diet and stress throughout life, may affect DNA methylation status and thus contribute to the risk of cancer development (Li et al., 2004). **The products of a number of hypermethylated genes have**

been implicated in prostate cancer development, including glutathione-*S*-transferase π *(GSTP1)*, adenomatous polyposis coli *(APC)*, retinoic acid receptors beta 2 *(RARβ2)*, and RAS association domain family protein isoform A *(RASSF1A)* (Mahapatra et al., 2012)**.**

GSTP1 belongs to a family of detoxifying enzymes that are involved in metabolic reduction of electrophilic carcinogens and was the first tissue methylation-biomarker to be discovered. Li et al. (2004) noted that the *GSTP1* gene was unmethylated in all normal human tissues and BPH but was hypermethylated in all 20 prostate cancer specimens analyzed. Harden et al. (2003a,b) used PCR to detect hypermethylated *GSTP1* in prostate biopsy specimens, and *GSTP1* methylation was detected in 11 of 15 (73% sensitivity) prostate cancer cases and in none of 14 (100% specificity) benign controls. Quantitation of *GSTP1* hypermethylation accurately detected CaP even in small, limited tissue samples. Elevated levels of *GSTP1* CpG hypermethylation have been detected in tissues from precancerous lesions (atypia and prostatic intraepithelial neoplasia [PIN]) and within ejaculates, urine, and plasma from men with prostate cancer (Bastian et al., 2005; Nakayama et al., 2003). Cairns et al. (2001) have demonstrated the presence of elevated *GSTP1* hypermethylation in up to 79% of prostate cancer specimens. *GSTP1* methylation appears to occur early in prostate carcinogenesis, and methylation levels may correlate with features of tumor aggressiveness (Jerónimo et al., 2001; Zhou et al., 2004). In a recent meta-analysis, *GSTP1* promoter hypermethylation was shown to have a sensitivity of 82% and specificity of 95% for distinguishing malignant from normal prostate tissue (Van Neste et al., 2012).

In addition to *GSTP1*, hypermethylation of other genes has also been noted to occur in close to 100% of prostate cancers (Mahapatra et al., 2012). *APC* is a tumor suppressor involved in apoptosis and cell migration, and mutation of *APC* is often an early event in the colon carcinogenesis. In a retrospective analysis assessing patients with newly diagnosed prostate cancer, *APC* methylation was associated with an independent 50% increase in the likelihood of death from prostate cancer (Richiardi et al., 2009). *RASSF1*, a gene involved in cell cycle regulation, and *RARβ2*, a nuclear transcriptional regulator, are other key genes methylated in a large proportion of prostate cancers and shown to distinguish benign from malignant prostate in a number of studies (Van Neste et al., 2012; Zon et al., 2009).

Perhaps the most clinically relevant aspect of these methylation changes is the discovery that they are frequently detectable in normal tissue adjacent to tumors but not in normal tissue well away from the primary tumor (Richiardi et al., 2013). Thus these changes may be useful indicators of the field effect that has long been known to exist: the presence of molecular changes in histologically normal tissue bordering a tumor. In patients with a prior negative biopsy, the identification of these molecular changes in the original biopsy tissue may suggest an increased likelihood of occult prostate cancer. Trock et al. (2012) showed that methylation of *APC* in histologically negative prostate biopsies predicted the presence of prostate cancer in 86 men undergoing repeat biopsy, with a negative predictive value (NPV) of 0.96 and sensitivity of 0.95. Using a quantitative commercial methylation assay (ConfirmMDx, MDxHealth, Inc.) that assesses methylation of *GSTP1*, *APC*, and *RASSF1*, Stewart et al. (2013) showed an NPV of 0.90 and sensitivity of 0.68. In this retrospective study, methylation status was an independent predictor of the presence of prostate cancer on repeat biopsy. Similarly, in a multi-institutional analysis of 350 subjects, Partin et al. (2014) demonstrated that the epigenetic assay assessing methylation of *GSTP1*, *APC*, and *RASSF1* resulted in an NPV of 88% (95% CI 85–91) in patients undergoing repeat prostate biopsy. In a recent analysis of 211 African-American men undergoing repeat prostate biopsy, ConfirmMDx was shown to have a sensitivity and specificity of 74.1% and 60.0%, respectively, for prostate cancer detection and 78% and 53%, respectively, for Gleason score ≥ 7 disease (Waterhouse et al., 2018). The NPVs for detection of all prostate cancer and Gleason score ≥ 7 disease were 78.8% and 94.2%, respectively. These findings suggest accurate identification of at-risk patients based on the “halo effect” of aberrant methylation.

Genomic Expression Profiles

For more than a decade, a great deal of attention has been devoted to discovering large sets of genes that, when evaluated together as a single biomarker assay, perform better than any individual gene on its own. Relatively recent advances in genomics have facilitated the evaluation of gene expression in formalin-fixed paraffin-embedded (FFPE) tissue, meaning prostate-archived prostate specimens can be interrogated for expression of gene profiles that are associated with aggressive disease features. Gene expression profiling has been explored in numerous settings, resulting in genomic classifiers for response to chemotherapy in breast and colorectal cancers (Del Rio et al., 2007; Iwao-Koizumi et al., 2005; Sparano et al., 2018).

A number of LDTs using genomic expression profiling for risk stratification in men with prostate cancer are now being developed and commercialized. This includes Prolaris (Myriad Genetics, Inc.), Oncotype Dx Prostate (Genomic Health, Inc.), and Decipher (GenomeDx Biosciences, Inc). The Prolaris test assesses 31 cell cycle progression (CCP) genes and 15 housekeeping genes, and a number of studies have demonstrated an association between this gene signature and the risk of progression and death from prostate cancer (Cuzick et al., 2011, 2012). Cuzick et al. (2012) reported that, in a conservatively managed cohort, Prolaris score was an independent predictor of prostate cancer specific death. In men who underwent subsequent prostatectomy, Bishoff et al. (2014) retrospectively assessed the performance of this assay on prostate needle biopsies and demonstrated that Prolaris score was an independent predictor of biochemical recurrence and metastasis. Recently, Cooperberg et al. (2013) incorporated the Prolaris score with the CAPRA score and reported improved performance for predicting biochemical recurrence after radical prostatectomy. Similarly, Prolaris score has been shown to predict outcomes in men undergoing external beam radiation therapy for prostate cancer, including prostate cancer–specific mortality (Freedland et al., 2013).

The Oncotype Dx Prostate classifier uses 12 cancer-related genes in 4 biologic pathways and 5 housekeeping genes to predict the likelihood of aggressive pathological features at the time of prostatectomy (Knezevic et al., 2013). This is defined as primary Gleason pattern 4 or pT3 disease at prostatectomy. Like Prolaris, Oncotype Dx is primarily intended to help with management decisions in patients with newly diagnosed prostate cancer regarding active surveillance or primary treatment and has been extensively validated for its clinical outcome (Cullen et al., 2015; Eure et al., 2017; Klein et al., 2014).

Last, the Decipher assay is a 22-marker genomic classifier initially developed for use in the post-prostatectomy setting (Erho et al., 2013). In men with high-risk disease and those with biochemical recurrence, the genomic classifier was demonstrated to be independently associated with the development of metastatic disease and prostate cancer–specific mortality (Karnes et al., 2013, 2018; Ross et al., 2014; Spratt et al., 2018). In a recent meta-analysis, Spratt et al. (2017) classified patients by Decipher as low-, intermediate-, and high-risk categories with 10-year cumulative incidence of metastases after radical prostatectomy of 5.5%, 15.0%, and 26.7% ($P < .001$), respectively. In this post-prostatectomy setting, Decipher may be used to guide decision making regarding adjuvant or salvage radiation therapy and retrospective data that patients with higher Decipher scores (≥0.4) may benefit from postoperative radiation (Dalela et al., 2017; Den et al., 2015; Gore et al., 2017). Building on these findings and using the GenomeDx Decipher database, Zhao et al. developed a 24-gene biomarker signature, PORTOS (Post-Operative Radiation Therapy Outcomes Score) to predict response to adjuvant radiation therapy. Decipher is now also available for clinical use in patients with newly diagnosed prostate cancer to potentially assist with initial management decisions, based on more recent biopsy data (Nguyen et al., 2017).

Although these tissue-based prognostic biomarker tests are increasingly used in the evaluation of patients with early stage prostate cancer to assess tumor aggressiveness, recent studies suggest that these assays may not be robust to tumor multifocality and heterogeneity. For example, Wei et al. (2017) observed discordant RNA expression profiles across distinct foci of prostate cancer obtained from the same patient. A more recent analysis of grade-discordant multifocal prostate cancer demonstrated that derived Prolaris, Oncotype Dx, and Decipher scores of low-grade prostate cancers do not predict the concomitant presence of an unsampled high-grade cancer from the same patient (Hovelson et al., 2018). Although there is likely a role for these tissue-based prognostic biomarkers in the management of prostate cancer, almost all of the published data have been from retrospective studies. The Genomics in Michigan ImpactiNg Observation or Radiation study is an ongoing prospective randomized trial assessing the impact of Decipher on decision making and outcomes after prostatectomy for men at high risk of local recurrence (NCT02783950).

Inherited Genetic Markers

Up to 40% to 50% of prostate cancer risk may be related to familial and hereditary factors (Lichtenstein et al., 2000). Familial prostate cancer is a broad term that encompasses 15% to 20% of cases and can include those patients with a strong family history of prostate cancer but no detectable genetic mutations (Giri and Beebe-Dimmer, 2016). Having a relative with prostate cancer increases risk of developing the disease by two- to fourfold (Goldgar et al., 1994; Liss et al., 2015). Single nucleotide polymorphisms (SNPs) are common genetic variants that may or may not have a functional role but are associated with an increased risk of prostate cancer and likely factor into many of these familial cases. Men possessing more than four prostate cancer–related SNPs have a 4.5-fold increase in risk of developing prostate cancer, and this risk increases to 10-fold for men with a family history of prostate cancer (Zheng et al., 2008). An example of SNPs being brought into practice is the STHLM3 biomarker test. This assay incorporates the four kallikreins that are part of the 4Kscore along with 232 risk SNPs and relevant clinical variables to form a composite prostate cancer early detection assay with an AUC of 0.74 for detecting Gleason score ≥7 prostate cancers (Eklund et al., 2018; Grönberg et al., 2015).

A number of genes have been implicated in heritable prostate cancer, most of which have important roles in the DNA damage repair machinery. These include *BRCA1*, *BRCA2*, *CHEK2*, *ATM*, and *PALB2*, along with mismatch repair mutations responsible for Lynch syndrome (*MLH1*, *MSH2*, *MSH6*, and *PMS2*). *BRCA1* and *BRCA2* are critical proteins in the process of homologous recombination, and pathogenic mutations in these genes have long been known to increase the risk of breast and ovarian cancers in women (Yoshida and Miki, 2004). More recently, *BRCA1* and *BRCA2* mutations in men have been associated with a significant increase in the risk of prostate cancer, and **men with pathogenic *BRCA2* mutations are diagnosed at a younger age, have higher Gleason grade tumors, and have a shorter median survival time than men with sporadic prostate cancers** (Mitra et al., 2008; Tryggvadóttir et al., 2007). For men under age 65 years, *BRCA1* carriers who have a 1.8-fold increased risk of prostate cancer and *BRCA2* carriers a 4.5-fold increased risk of prostate cancer compared with noncarriers (Thompson et al., 2002). Across all ages, Kote-Jarai et al. (2011) report an **estimated 8.6-fold increased risk of prostate cancer in *BRCA2*-positive men**. Although Lynch syndrome is well known to be associated with colorectal, liver, skin, and upper urinary tract cancers, **men with Lynch syndrome are also at an increased risk of developing prostate cancer.** A study of 821 male Lynch syndrome carriers reported a 10-fold increase in relative risk of prostate cancer for *MSH2* carriers (Barrow et al., 2013).

Other key genes include *ATM* and *CHEK2*, involved in double-strand DNA break repair, as well as the homeobox protein HOXB13, and all of these may be used as a potential marker of prostate cancer risk. The Hale et al. (2014) pooled analysis of five studies shows that *CHEK2* carriers have a prostate cancer odds ratio of 1.98 and 3.39 in unselected and familial cases, respectively. The *HOXB13 G84E* variant was identified as a key prostate cancer risk gene through familial linkage studies, and the relative risk for prostate cancer increases in mutation carriers by 4.5-fold (Ewing et al., 2012; Huang and Cai, 2014). There is no evidence that *HOXB13* increases the risk of aggressive cancers, however.

Next generation sequencing (NGS)–based testing is clinically available for

single genes such as for *BRCA1* or *BRCA2*, but multi-gene panel testing has become more common in the absence of a known familial mutation. For prostate cancer, these panels typically include *BRCA1*, *BRCA2*, *ATM*, *CHEK2*, *MLH1*, *MSH2*, *TP53*, and *EPCAM*, among others specific to the individual commercial platform. Importantly, although many of the genes included in these panels have a clear association with prostate cancer risk, others carry a still unknown clinical significance with poorly defined cancer risk. National Comprehensive Cancer Network (NCCN) recommendations focus on *BRCA* testing at this point (Hall et al., 2014). Identification of *BRCA* mutations—or potentially these other mutations causing increased prostate cancer risk—could have important implications for early detection and management of patients at high risk of developing prostate cancer (Bancroft et al., 2014).

Summary

Early detection when cancer remains confined to the prostate not only improves cure rates but also decreases mortality from this disease. Although the discovery and application of PSA have revolutionized current prostate cancer detection and management, stage migration and changes in the natural history of this cancer have outrun the currently maximized application of this tumor marker. Application of various PSA derivatives, although improving sensitivity, risks impairing specificity. The discovery of molecular derivatives of PSA, PCA3, new kallikrein markers, and gene rearrangements are leading to significant improvements in the efficiency of prostate cancer detection.

Innovations and new understanding in the field of molecular oncology have provided a host of potential prostate cancer tumor markers. Because prostate cancer has been shown to be a heterogeneous disease, application of a panel of markers will probably ultimately provide added sensitivity and specificity for detection of the disease. Identification of hypermethylated regions, such as for *GSTP1*, as well as tissue-based genomic classifiers may substantially improve the diagnostic and prognostic potential of prostate needle biopsies. Development of these markers from research into clinically applicable tools will require clear demonstration of clinical validity and clinical utility, showing that these new assays have a real impact in the clinical care of men with prostate cancer.

Key Points

- PSMA has been identified in the central nervous system, intestine, and prostate and now serves as an important target for advanced molecular imaging.
- PSA is a member of the human kallikrein gene family. PSA and human kallikrein-2 have been used in prostate cancer detection.
- Ectopic expression of PSA occurs in breast tissue, adrenal, and renal carcinomas.
- PSA is organ specific, not disease specific; its half-life is 2 to 3 days.
- 5α-reductase inhibitors reduce serum PSA by 50%.
- Prostate cancer cells make less PSA than normal prostate tissue, gram for

gram. PSA expression is strongly influenced by androgens. Ejaculation can lead to a false increase in PSA.

- Seventy percent of serum PSA is bound to three proteins: α_2-macroglobulin, α_1-protease inhibitor, and α_1-antichymotrypsin. Patients with prostate cancer have a higher fraction of circulating PSA bound to these proteins, that is, they have a lower free PSA.
- When PSA is released from the cell, a portion of an attached amino acid chain is cleaved, leaving a smaller amino acid chain attached, which inactivates its biologic activity. This molecule is termed proPSA. When this amino acid chain is cleaved from proPSA, PSA becomes active as a serum protease. ProPSA may be used to diagnose prostate cancer.
- PCA3 is a urine-based marker used in the diagnosis of prostate cancer. It can be combined with detection of the TMPRSS2:ERG gene fusion to improve diagnostic accuracy.
- Circulating tumor cells and circulating tumor DNA are promising sources of biomarkers, particularly in advanced prostate cancer.
- Tissue-based gene expression signatures are commercially available and can be performed on small amounts of formalin-fixed paraffin-embedded tissue and may provide additional prognostic information beyond Gleason score and other clinical parameters.
- Prostate cancer susceptibility genes have been located on a number of chromosomes increase the risk of developing prostate cancer.
- Key inherited genes with moderate penetrance that increase the risk of aggressive prostate cancer are *BRCA1*, *BRCA2*, and *ATM*. These are all DNA damage repair genes.

Prostate Biopsy

Techniques and Imaging

Edouard J. Trabulsi MD, FACS, Ethan J. Halpern MD, MSCE, Leonard G. Gomella MD, FACS

Transrectal ultrasonography (TRUS) of the prostate has become a standard tool in the practice of urology. Many image-guided prostate cancer interventions, including initial prostate biopsy, follow-up biopsy for active surveillance, low- and high-dose brachytherapy, cryotherapy, and high-intensity focused ultrasonography rely on TRUS. Fiducial and radiofrequency markers are being placed under TRUS guidance for real-time tumor tracking of the prostate during radiation therapy (Das et al., 2014; Linden et al., 2009). Polyethylene glycol hydrogel injection into anterior perirectal fat before prostate radiation therapy to decrease radiation dose is another new and evolving TRUS application (Strom et al., 2014) and has shown decreased rectal dose and improved rectal toxicity (Mariados et al., 2015). TRUS also has a role in benign conditions such as in the evaluation of treatment options for benign prostatic hyperplasia (BPH) and in some cases of male infertility. This chapter focuses primarily on the most common use of TRUS, namely prostate biopsy for the diagnosis of prostate cancer.

The detection and diagnosis of prostate cancer has benefited greatly from prostate-specific antigen (PSA) screening efforts along with the introduction and refinement of systematic TRUS-guided prostate biopsy techniques. However, these prostate cancer screening efforts are not without controversy (Gomella et al., 2011). When a decision is made to perform a diagnostic prostate biopsy, the 12-core TRUS prostate biopsy with local anesthesia is considered the preferred and current standard of care technique (Bjurlin et al., 2013).

Watanabe et al. (1968) was first to describe TRUS of the prostate. **The use of digitally directed prostate biopsy, common until the late 1980s, evolved into**

the expanded clinical use of TRUS-directed prostate biopsies. Improvements in ultrasound technology continued with the important introduction of the TRUS-guided systematic sextant (six core) biopsy protocol by Hodge et al. (1989). Concurrent with improved biopsy techniques including the increase in recommended biopsy cores to 12, the use of PSA screening increased the number of men undergoing early prostate cancer screening and prostate biopsy. Current estimates are that up to 1.3 million biopsies are performed annually in the United States alone (Aubry et al., 2013). Given the prevalence of clinically significant and insignificant prostate cancer and the frequency with which TRUS-guided prostate biopsies are performed, significant efforts have been focused on determining the appropriate indications for biopsy, the ideal technique by which to image and perform biopsy of the prostate, and how to best limit complications.

Ultrasonographic Anatomy of the Prostate

The prostate lies between the bladder neck and the urogenital diaphragm, just anterior to the rectum, an ideal position to be imaged via TRUS. The prostate gland is traditionally described based on a pathologic zonal architecture. These divisions consist of the anterior fibromuscular stroma, which is devoid of glandular tissue; transition zone (TZ); central zone (CZ); periurethral zone; and peripheral zone (PZ). Unfortunately, these regions are not visible sonographically as distinct entities (Halpern, 2002) (Fig. 150.1).

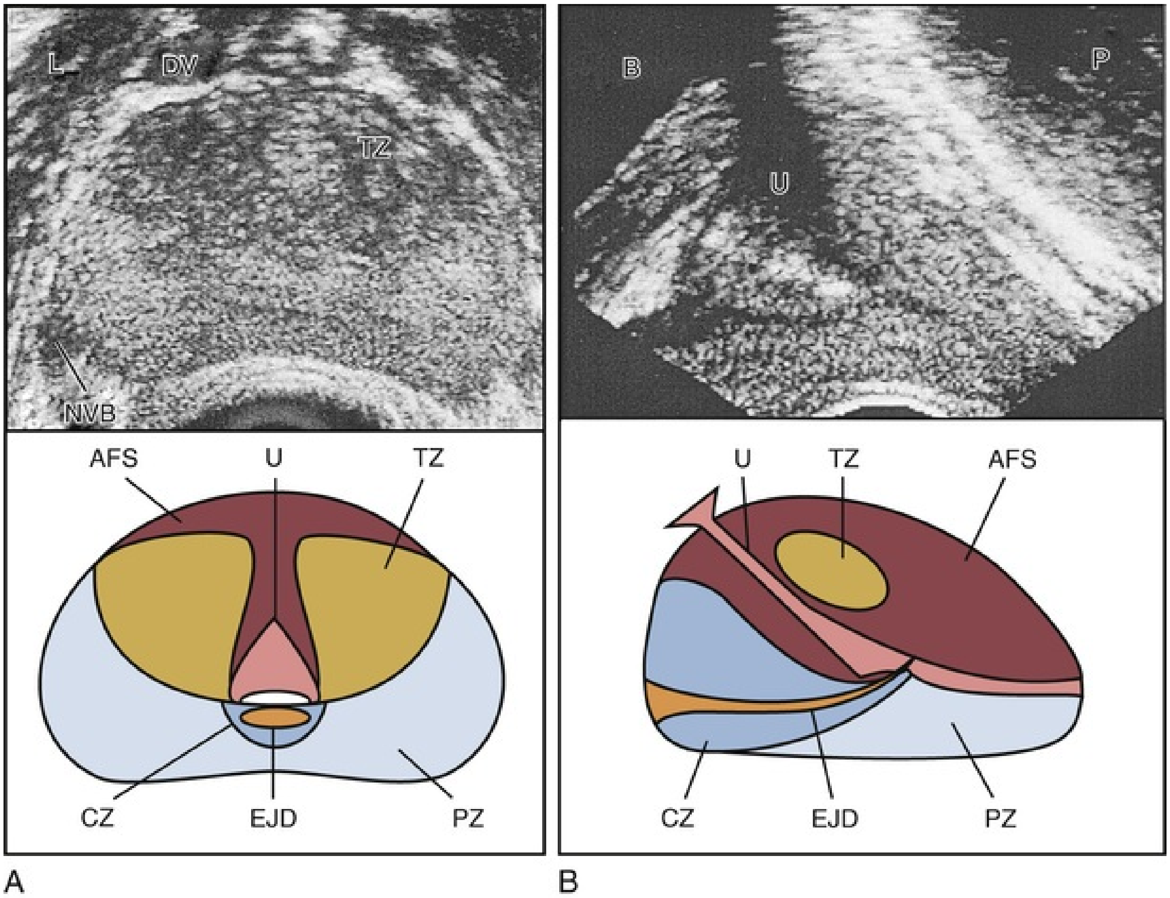

FIG. 150.1 Normal prostate ultrasound images *(top)* with diagrams *(bottom)* at approximately the level of the verumontanum demonstrating zonal anatomy. (A) Transverse view. (B) Sagittal view. *AFS,* anterior fibromuscular stroma; *B,* bladder; *CZ,* central zone; *DV,* dorsal vein complex; *EJD,* ejaculatory ducts; *L,* levator muscles; *NVB,* neurovascular

bundle; *PZ,* peripheral zone; *TZ,* transition zone; *U,* urethra.

However, the TZ often may be discernible from the PZ and CZ, particularly in glands with significant BPH. Located posteriorly, the normal CZ and PZ, from which a majority of adenocarcinomas arise, have a homogeneous echogenic appearance, whereas the anteriorly situated TZ is more heterogeneous. **Frequently, calcifications along the surgical capsule known as the *corpora amylacea* highlight the plane between the PZ and TZ (multiple diffuse calcifications are a normal, often incidental ultrasonographic finding in the prostate and represent a result of age rather than a pathologic entity.** Larger prostatic calculi associated with symptoms may be related to underlying infection or inflammation and require further evaluation (Geramoutsos et al., 2004).

The prostatic urethra traverses the length of the gland in the midline and thus must be imaged in the sagittal plane to be simultaneously viewed along the entirety of its course (Fig. 150.2A and B). The distended urethral lumen has a hypoechoic appearance, whereas periurethral calcifications may produce a thin echogenic outline. The smooth muscle of the internal sphincter extends from the bladder neck, encircling the urethra to the level of the verumontanum. These muscle fibers may be visualized sonographically as a hypoechoic ring around the upper prostatic urethra, giving it a funneled appearance proximally as it arises from the bladder neck. On reaching the verumontanum, the urethra angles anteriorly and runs through the remainder of the gland to exit at the apex of the prostate. This angle gives the prostatic urethra an anteriorly concave appearance when viewed along its entire course in the sagittal plane.

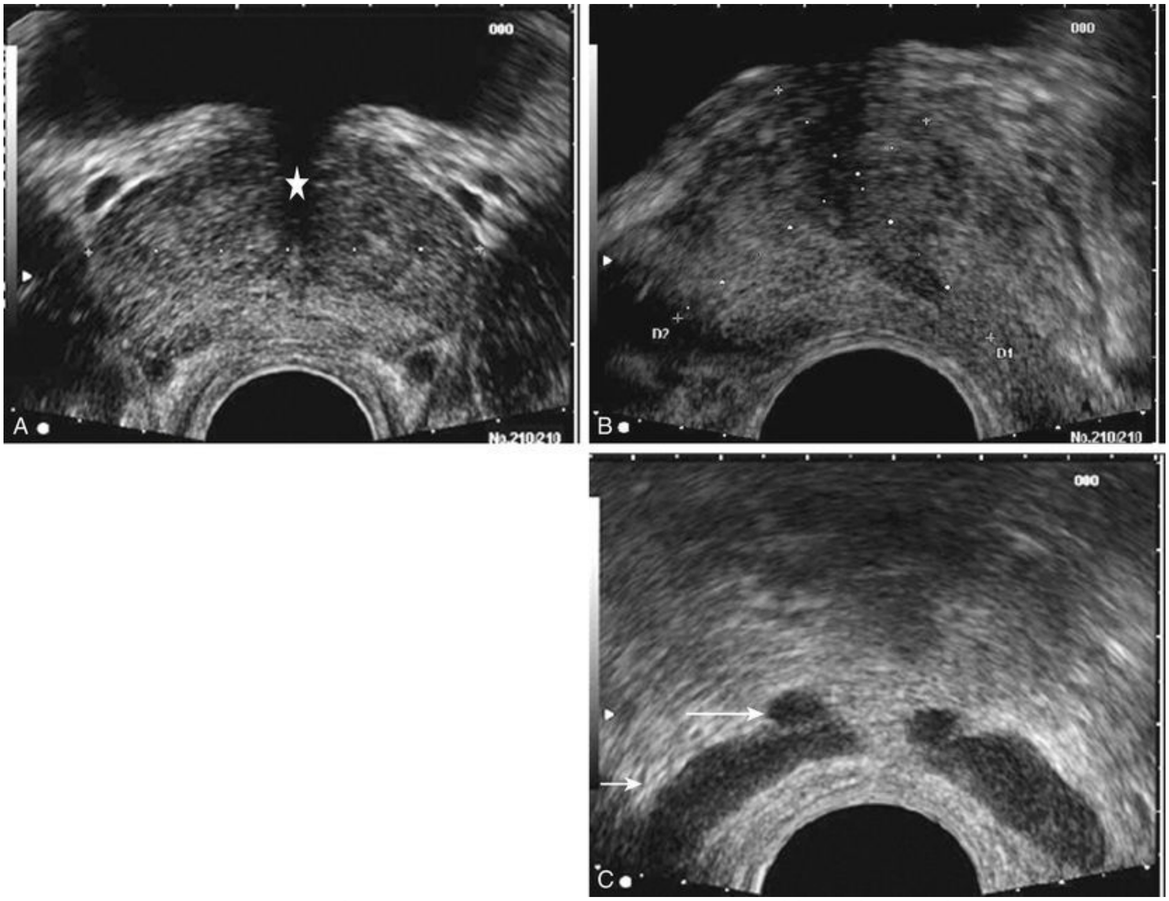

FIG. 150.2 Classic gray-scale transrectal ultrasound imaging of the prostate. (A) In the transverse plane, the hypoechoic urethra centrally located *(star)* and *dotted line* (between calipers) represent transverse measurement. (B) Midline sagittal view with the hypoechoic urethra running the length of the gland. D1 represents longitudinal measurement, and D2 represents anteroposterior measurement. (C) Seminal vesicles *(long arrow)* and vasa deferentia *(short arrow)* in the transverse plane.

The paired seminal vesicles (SVs) are positioned posteriorly at the base of the prostate (see Fig. 150.2C). **They have a smooth, saccular appearance and should be symmetrical. The normal SV measures 4.5 to 5.5 cm in length and 2 cm in width.** A cystic SV mass is presumptively benign, whereas a solid lesion has a very small probability of being malignant, especially if the patient has a primary neoplasm elsewhere. Schistosomiasis should be considered when making a differential diagnosis in patients who live in areas where infestation is endemic and have a solid SV mass (Al-Saeed et al., 2003). An absent SV is associated with a 79% ipsilateral renal agenesis. In the transverse plane, the vasa deferentia course just above their ipsilateral SV before diving caudally toward the prostate near the midline. Here they lie just medial to the tapering ipsilateral

SV before the two structures fuse to form an ejaculatory duct. The ejaculatory ducts (occasionally seen as a hypoechoic structure) enter the gland posteriorly and empty into the urethra at the verumontanum (see Fig. 150.2C). Their course parallels that of the prostatic urethra distal to the verumontanum.

Gray-Scale Transrectal Ultrasonography

Gray-scale TRUS has become the most common imaging modality for the prostate. Most commonly used for prostate cancer detection, TRUS also may be used in the evaluation of other conditions, such as infertility, or basic prostate volume measurements for interventions such as brachytherapy or in the management of BPH.

Commercially available endorectal probes are available in both side- and end-fire models and transmit frequencies of 6 to 10 MHz. Most modern US machines have optimized self-programming for TRUS and biopsy. Some newer biplane probes provide simultaneous sagittal and transverse imaging modes. Probes provide a scanning angle approaching 180 degrees to allow simultaneous visualization of the entire gland in both the transverse and sagittal planes. Increasing probe frequency is associated with increased spatial resolution. As the frequency of the probe is increased, the portion of the image that is in focus (focal range) is closer to the transducer (Kossoff, 2000). The commonly used 7-MHz transducer produces a high-resolution image with a focal range from 1 to 4 cm from the transducer (best for the PZ, where most cancers arise). Lower-frequency transducers (e.g., older 4-MHz transducers) have a focal range from 2 to 8 cm but at lower resolution. Lower-frequency transducers improve anterior delineation of large glands, increasing the accuracy of volume measurements, but provide poor internal architecture visualization. Many modern TRUS systems have an adjustable transmit frequency that may be varied during the examination, depending on the imaging depth of most interest.

Acoustic properties of soft tissue are similar to those of water, but clinically useful ultrasound energy does not propagate through air. For this reason, a water-density substance, termed a *coupling medium*, is required. The coupling medium, usually sonographic jelly or lubricant, is placed between the probe and the rectal surface. If the probe is covered with a protective condom, the coupling medium is placed between the probe and the condom, and between the condom and the rectal surface.

Various studies have compared the TRUS biopsy prostate cancer detection rates using the end-fire or side-fire probes. Prospective studies have confirmed that there is no significant difference in positive biopsy rates in the initial or repeat biopsy setting (Raber et al., 2012). However, in this study, the side-fire transrectal probe was associated with better patient tolerance.

Machine Settings

The image magnification should be adjusted so that most of the prostate is sufficiently magnified to allow detection of relevant abnormalities. In general, the magnification is low during prostate measurements so that the entire gland is visible on a single screen. During biopsies, magnification is increased to optimize visualization of needle passage. The ultrasonographer can manually alter the brightness (or gain) slightly with each new patient and occasionally during imaging of different areas within the same prostate. **The optimal brightness setting results in a medium-gray image of the normal PZ. This gray tone serves as the reference point for judging lesions as hypoechoic (darker than the normal PZ), isoechoic (similar to the normal PZ), hyperechoic (lighter than the normal PZ), or anechoic (completely black).**

Techniques

The complete TRUS evaluation of the prostate includes scanning in both the sagittal and transverse planes to obtain a volume calculation. The CZ and PZ are inspected for hypoechoic lesions and contour abnormalities, the periprostatic fat planes are evaluated, and the SVs and vasa deferentia are fully visualized.

Probe Manipulation

Patients are usually scanned in the left lateral decubitus position (see the Patient Positioning section later in this chapter) **to examine both the transverse and the sagittal planes.** There are two approaches to probe manipulation for transverse imaging (see Fig. 150.2A). With radial and some biplane probes, advancing the probe cephalad into the rectum images the prostate base, the SVs, and the bladder neck. Pulling the probe caudally toward the anal sphincter yields images of the prostatic apex and proximal urethra. Transverse imaging with end-fire, side-fire, and some biplane probes is accomplished by angling the handle of the probe right or left using the anal sphincter as a fulcrum (see Fig. 150.2B). Angling the probe toward the scrotum produces more cephalad images, and angling the probe toward the sacrum produces more caudal images.

There are also two approaches to probe manipulation for sagittal imaging. One method is rotation of the probe. Clockwise rotation yields images of the left side of the prostate, and counterclockwise rotation yields images of the right side; this method is generally employed for side-fire probes. Alternatively, sagittal imaging can be accomplished by angling the probe up or down using the anal sphincter as a fulcrum; this method is generally employed for end-fire probes. In the left lateral decubitus position, angling the handle of the probe down (toward the floor) yields images of the right side of the prostate, and angling the handle of the probe up (toward the ceiling) yields images of the left side. Urologists often prefer angling the probe because this method is similar to manipulation of a cystoscope and is less uncomfortable for the patient.

Joint guidelines concerning the reprocessing of equipment used for TRUS biopsy have been published in a joint American Urological Association (AUA)/Society for Urological Nurses and Associates (SUNA) white paper (American Urological Association, 2016).

Volume Calculations

A variety of formulas are used to calculate prostate volume and require measurement of up to three prostate dimensions. In the axial plane, the transverse and anteroposterior (AP) dimensions are measured at the point of widest transverse diameter (see Fig. 150.2A and B). The longitudinal dimension is measured in the sagittal plane just off the midline because the bladder neck may obscure the cephalad extent of the gland (see Fig. 150.2B). Most formulas assume that the gland conforms to an ideal geometric shape: either an **ellipse** ($\pi/6 \times$ transverse diameter $\times$ AP diameter $\times$ longitudinal diameter), **sphere** ($\pi/6 \times$ transverse diameter^3), or **prolate (egg-shaped) spheroid** ($\pi/6 \times$ transverse diameter$^2 \times$ AP diameter). Despite the inherent inaccuracies that arise from these geometric assumptions, all formulas reliably estimate gland volume and weight, with correlation coefficients greater than 0.90 with radical prostatectomy specimen weights, because 1 cm^3 equals approximately 1 g of prostate tissue (Terris and Stamey, 1991). **The mature prostate is between 20 and 25 g and remains relatively constant until approximately 50 years of age, when the gland enlarges in many men; the average prostate volume in a 60- to 70-year-old individual is approximately 48 g** (Griffiths, 1996).

Prostate volume determination can be an important aspect of assessment for benign prostatic hyperplasia (BPH) with lower urinary tract symptoms (LUTS) (see Chapters 144 to 146 for a detailed discussion of BPH). Accurate size calculation may affect the surgical technique when surgical intervention is considered for men with BPH failing medical therapy. As indicated in the AUA guideline “Surgical Management of Lower Urinary Tract Symptoms Attributed to Benign Prostatic Hyperplasia” released in 2018, the assessment of prostate size by TRUS or cross-sectional imaging should be considered before surgical intervention (Foster et al., 2018). This consensus guideline noted that minimally invasive surgical techniques for BPH are most effective for prostate volumes between 30 and 80 g, with larger prostate volumes best served with open, laparoscopic, or robotic enucleation procedures, further highlighting the importance of accurate volume determination.

Planimetry may be employed when a more precise determination of gland volume is required, such as for brachytherapy planning. With the patient in the lithotomy position, the probe is mounted to a stepping device and serial transverse images are obtained at set intervals (e.g., 3 to 5 mm) through the entire length of the gland. The surface area of each serial image is determined, and the sum of these measurements is then multiplied by total gland length to yield the prostate volume.

Prostate gland volume can be used to calculate derivatives such as the PSA density (PSAD = serum PSA/gland volume). PSAD is a method to differentiate benign versus malignant disease with an elevated PSA and benign digital rectal examination. Higher PSA density values (>0.15 ng/mL/cc) are more suggestive of prostate cancer; lower values suggest BPH. An elevated PSAD has a sensitivity and specificity of 75% and 44%, respectively, for predicting cancer on repeat biopsy (Djavan et al., 2000). Unfortunately, there is high interoperator and intraoperator variability in PSAD determinations, and similar predictive information now can be obtained using serum free-to-total PSA ratio (Djavan et al., 2003).

Cystic Lesions of the Prostate

Cystic prostatic structures are common on TRUS. Simple cysts have the same sonographic appearance as in any other part of the body: they are thin walled, are anechoic, and show acoustic enhancement beyond the cyst. Prostatic cysts may be congenital or acquired but are rarely clinically significant, regardless of cause.

Congenital prostatic cystic lesions may arise from either Müllerian (Müllerian duct cysts and prostatic utricles) or Wolffian (ejaculatory duct and SV cysts) structures. An enlarged prostatic utricle is a diverticular projection from the posterior urethra at the level of the verumontanum (Cochlin, 2002) and appears as a midline anechoic structure. These are associated with genital anomalies, including hypospadias (most common), ambiguous genitalia, undescended testes, and congenital urethral polyps (Gregg and Sty, 1989). Müllerian duct cysts also appear as midline anechoic lesions that result from failure of the Müllerian ducts to fuse with the urethra. They are generally ovoid to pear shaped, with the cyst neck oriented toward the verumontanum. When Müllerian duct cysts are present, men should be evaluated for unilateral renal agenesis (McDermott et al., 1993).

Lateral paraprostatic cystic structures include SV and vas deferens cysts (Wolffian in origin). Ejaculatory duct cysts are typically small, lie off of the midline, and may accompany ejaculatory duct obstruction/obliteration with azoospermia (Fig. 150.3). SV cysts can be caused by congenital or acquired obstruction of the ejaculatory duct and are associated with cystic renal disease; up to two-thirds of men with SV cysts also may have renal agenesis (King et al., 1991). Acquired cysts of the TZ result from hemorrhagic degeneration of BPH nodules (Hamper et al., 1990), whereas those of the outer gland have no proven cause.

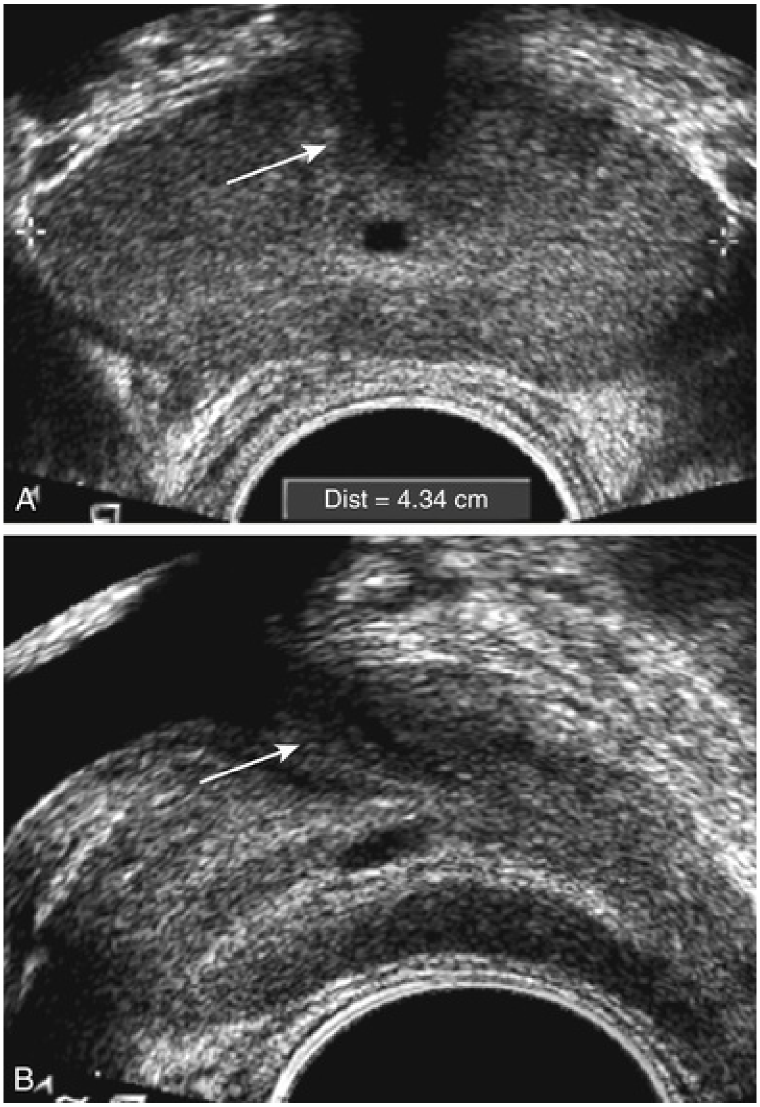

FIG. 150.3 A hypoechoic midline cystic structure *(arrow)* arising from the ejaculatory duct is shown in the transverse (A) and sagittal (B) planes and demonstrates through-transmission classic for simple cysts.

Prostate Cancer Imaging on Transrectal Ultrasonography

In early TRUS studies, hypoechoic lesions were considered pathognomonic for prostate cancer. All hypoechoic lesions within the PZ should be noted and included in the biopsy material (Fig. 150.4). However, the lack of a distinct hypoechoic focus does not preclude proceeding with biopsy, because 39% of all cancers are isoechoic, and up to 1% of tumors may be hyperechoic on conventional gray-scale TRUS (Shinohara et al., 1989). A study of almost 4000 men revealed that prostate cancer was detected in 25.5% with a hypoechoic lesion and in 25.4% without such a lesion, with a per-core distinction of 9.3% for hypoechoic and 10.4% for isoechoic areas for cancer (Onur et al., 2004). Conversely, another study noted that biopsy samples taken when a prostate lesion is identified by TRUS are almost twice as likely to show cancer than when no lesion is visible (Toi et al., 2007). They concluded that the search for and targeting of hypoechoic lesions on TRUS remains important for prostate cancer diagnosis. Other disease processes such as granulomatous prostatitis (Terris et al., 1997), prostatic infarct (Purohit et al., 2003), and lymphoma (Varghese and Grossfeld, 2000) may produce hypoechoic lesions. There is a need to perform a biopsy on hypoechoic lesions, but these lesions are not pathognomonic for cancer as once thought.

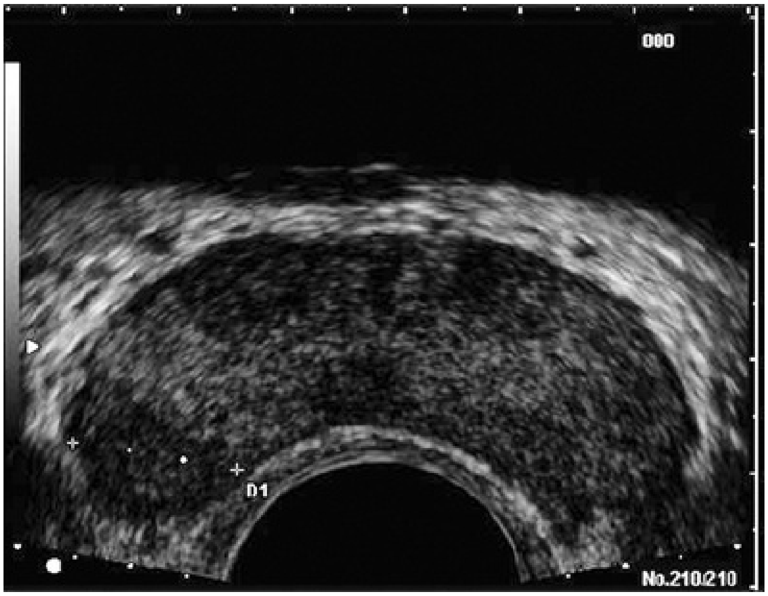

FIG. 150.4 Classic hypoechoic peripheral zone lesion *(dotted line between calipers)* in the right mid-gland that transrectal ultrasound–guided biopsy proved to be a Gleason 3 + 3 = 6 adenocarcinoma.

Any focal contour abnormalities along the outer edge of the gland and any asymmetries in echotexture from the PZ of one lobe to that of the other are noted. **Extracapsular extension of prostate cancer, although not well visualized if present as a microfocus, is suggested by a focal loss of the typically bright white periprostatic fat.**

Key Points: Gray-Scale Transrectal Ultrasonography

- TRUS technology has become a mainstay of many image-guided prostate interventions, including prostate biopsy, brachytherapy, cryotherapy, and high-intensity focused ultrasonography.
- The classic zonal anatomy of the prostate is not evident on TRUS, but the PZ typically may be distinguished from the TZ, allowing biopsies to be reliably aimed toward the more commonly cancer-bearing PZ.
- Benign cystic lesions of the prostate typically demonstrate thin-walled architecture with sonographic through-transmission and may become symptomatic if infected.
- Several formulas exist for determining prostate volume on TRUS. For highly accurate volume determinations such as for brachytherapy, planimetry using a template is required.
- Hypoechoic foci seen on gray-scale TRUS should be considered suggestive of adenocarcinoma of the prostate and included in the biopsy specimen. However, up to 39% of cancers are not visible on routine gray-scale ultrasound imaging.

Transrectal Ultrasonography Appearance After Treatment

External-beam radiation monotherapy usually results in decreased volume by 6 months after treatment. Irradiated prostates are diffusely hypoechoic, with poorly defined anatomy. Large hypoechoic tumors, particularly those not responding to therapy, show little change in echogenicity once irradiated, but smaller foci responding well to therapy tend to become isoechoic (Egawa et al., 1991). TRUS findings in general correlate poorly with pathologic findings and outcomes in irradiated prostates.

Initial postimplantation edema followed by long-term changes occurs with interstitial brachytherapy, as with external-beam radiation therapy (Whittington et al., 1999). With an ideal permanent implant, seeds should be distributed evenly throughout the gland, with periurethral sparing and no errant seeds outside of the prostate gland. These seeds are hyperechoic and demonstrate posterior shadowing. The prostate volume declines significantly after treatment, with a 37% size reduction at 1 year after treatment and over 50% reduction 8 years after implantation (Stone and Stock, 2007). This decline appears unaffected by the use of neoadjuvant hormonal therapy.

Androgen ablation with luteinizing hormone–releasing hormone analogues will cause an average 30% volume decrease with androgen deprivation in prostates with and without cancer (Whittington et al., 1999). The decrease ranges up to 60% in large glands and as little as 10% in small glands. Volume decreases by approximately 21% at 6 months using 5α-reductase inhibitors such as finasteride (Marks et al., 1997).

Post–radical prostatectomy TRUS is considered normal if there is smooth tapering of the bladder neck to the urethra (Kapoor et al., 1993). Many patients demonstrate a nodule of tissue anterior to the anastomosis, representing the ligated dorsal vein complex (Goldenberg et al., 1992). A nodular appearance of the bladder neck at the anastomosis may also be related to the surgical purse-string technique that is used to match the anatomically larger orifice of the bladder neck to the smaller diameter of the urethra. Any hyperechoic or hypoechoic lesions or interruptions of the retroanastomotic fat plane are considered suspicious (Kapoor et al., 1993). Hypoechoic lesions have been reported in 75% to 95% of patients with locally recurrent cancer, and color Doppler has been used to improve cancer detection in the prostatic fossa (Tamsel et al., 2006). Patients with detectable PSA who are candidates for salvage radiation therapy were once considered for routine biopsy of the anastomotic area. **Biopsy of the anastomotic region with PSA-indicated recurrence in the absence of a palpable nodule is not usually informative** (Scattoni et al., 2004). However, biopsy of an abnormality seen on TRUS, even with a normal digital rectal examination, can be diagnostic of locally recurrent disease (Naya et al., 2005).

Transrectal Ultrasonography and Other Malignancies

Prostatic involvement with transitional cell carcinoma (TCC) from the bladder is generally not detectable by TRUS, but 71% of prostatic stromal TCC lesions are hypoechoic. Prostatic TCC detected by TRUS must be confirmed by biopsy because granulomas resulting from instillation of bacillus Calmette-Guérin are common in patients with urothelial carcinoma and also are hypoechoic (Terris et al., 1997).

Extension of squamous cell carcinoma (SCC) to the prostate from the bladder or urethra is much more common than primary prostatic SCC. Prostatic SCC appears as an irregular, anterior mass demonstrating relative hyperechogenicity (Terris, 1999).

Adenoid cystic/basal cell carcinoma of the prostate is rare but potentially fatal. Histologically, cribriform or adenoid cystic patterns predominate. Numerous cystic glands give this tumor an unusual appearance on TRUS, characterized by multiple, evenly distributed, small anechoic cysts (Iczkowski et al., 2003).

Prostatic sarcoma TRUS appearance is typified by an irregular, hypoechoic mass with an anechoic area consistent with necrosis (Terris, 1998). The echogenicity of rhabdomyosarcoma is similar to that of normal prostate tissue. Hematologic and lymphoid malignancies involving the prostate are generally not visualized with TRUS (Terris and Freiha, 1998). Biopsy specimens may demonstrate a lymphocytic infiltrate, but this is often attributed to chronic inflammation if no suspicion of nonprostate malignancy exists. Bladder wall thickening can be seen on TRUS of the prostate and is often associated with bladder wall hypertrophy associated with BPH. Bladder thickening may also suggest malignancy of the bladder as does an incidentally discovered bladder mass.

Prostate Biopsy: Techniques and Outcomes

Indications for Prostate Biopsy

A detailed discussion of the controversy concerning screening asymptomatic men for prostate cancer is discussed elsewhere in this book. Before TRUS improvements and PSA testing became widespread, clinicians relied mainly on digital rectal examination to establish a suspicion of prostate cancer and performed digitally directed lesional biopsies. **PSA-based screening of asymptomatic men has resulted in the adaptation of TRUS biopsy as the standard of care when prostate biopsy is used to identify prostate cancer** (Bjurlin et al., 2013). In general, the TRUS without a biopsy has little utility in the evaluation of a patient for prostate cancer. Overall it estimated that an initial prostate biopsy carries a 30% rate of detecting prostate cancer. **Fine-needle aspiration biopsy is no longer considered state-of-the-art in the diagnosis of prostate cancer** (Heidenreich et al., 2014).

Early prostate cancer detection was markedly improved by PSA-based screening programs. These initiatives increased the rate of organ-confined and potentially curable disease (Catalona et al., 1993). The improvements led to the unintended consequence of the overdiagnosis and overtreatment of clinically insignificant cancers in many men. Historically, many clinicians would recommend prostate biopsy once a patient's serum PSA level rose above 4.0 ng/mL. **Subsequent data from the Prostate Cancer Prevention Trial demonstrated that there is no safe PSA threshold that can rule out prostate cancer in any age range** (Thompson et al., 2005). When examining men whose serum PSA level was 4.0 ng/mL or less, significant numbers were diagnosed with prostate cancer at all PSA levels, with an overall prostate cancer detection rate of 15% for all men with a PSA level less than 4.0 ng/mL and nearly 15% having a Gleason score of 7 or greater (Thompson et al., 2004).

Clinical trials that have attempted to provide an answer to the benefits of PSA screening have only added to the controversy (Gomella et al., 2011). Results from the European Randomized Screening for Prostate Cancer (ERSPC) demonstrated a net benefit, whereas the US-based Prostate, Lung, Colorectal, and Ovarian (PLCO) Cancer Screening Trial showed no benefit on prostate cancer–specific survival (Hayes and Barry, 2014). A recent analysis of the PLCO and ERSPC trials using mean lead time estimates concluded that both studies “provide compatible evidence that screening reduces PCa mortality” (Tsodikov et al., 2017). An accompanying editorial concludes “The controversy about PSA-based screening should no longer be whether it can do good, but whether we can change our behavior so that it does more good than harm” (Vickers, 2017). Recommendations by organizations vary greatly on screening asymptomatic men for prostate cancer, with some supporting screening based on informed decision making and others rejecting the performance of PSA-based screening in an asymptomatic man (Gomella et al., 2011; Hayes and Barry, 2014). Considerations concerning overall health, age of the patient, family history, therapeutic options, wishes of the patient, and other risk factors all need to be considered in recommending prostate biopsy. In addition, concerns are growing over the potential morbidity and mortality of prostate biopsy (Zlotta and Nam, 2012). A variety of online nomograms are available that may help with decision making (Nguyen and Kattan, 2013).

Organizations such as the AUA recommend shared decision making for men 55 to 69 years of age considering PSA-based screening, a target age group for whom benefits may outweigh harms (Carter et al., 2013). Outside this age range, the AUA recommends that PSA-based screening as a routine could not be recommended based on the available evidence. **Most organizations have abandoned absolute PSA level cutoff values for prostate biopsy and are relying increasingly on risk stratification approaches and changes in PSA level over time.** Men at elevated risk for having prostate cancer are those older than 50 years of age; those who have a family history of prostate cancer and are older than 45 years of age or African-American; or those with a PSA level greater than 1 ng/mL at 40 years of age and greater than 2 ng/mL at 60 years of age (Heidenreich et al., 2014).

Adjuncts to serum PSA testing have been advocated to improve the performance characteristics of PSA for prostate cancer detection, including free-to-total PSA ratio, PSA velocity, and PSAD, but are not uniformly reliable (Heidenreich et al., 2014). The National Comprehensive Cancer Network (NCCN) advocates the selective use of biomarkers, including PSA derivatives, tissue assays of stromal hypermethylation (Confirm MDx), as well as urinary assays for ERG (MiPS, ExoDx) and PCA3 in the decision to perform TRUS biopsy (NCCN, 2018). In the appropriate patient for prostate cancer screening, the NCCN recommends TRUS prostate biopsy in the following situations:

positive digital rectal examination regardless of PSA level; PSA level 4 to 10 ng/mL based on patient risk benefit; PSA level 2.5 ng/mL or less and PSA velocity 0.35 ng/mL or greater per year; PSA level 2.6 to 4.0 ng/mL; and PSA level 4.0 ng/mL or greater, especially if the free PSA level is 10% or less. As recommended by the NCCN, the presence of nodules on digital rectal examination usually should prompt TRUS biopsy regardless of PSA levels. In a recent study, 14% of cancers were diagnosed based on digital rectal examination alone (Okotie et al., 2007). However, the American Cancer Society guidelines now suggest that prostate cancer screening can be performed with or without a rectal examination (Smith et al., 2014). In 2018, the US Preventive Services Task Force (USPSTF) issued a new recommendation statement on screening patients for prostate cancer that for men 55 to 69 years of age, the decision to undergo PSA-based screening for prostate cancer should be an individual one with discussion of the risks and benefits (USPSTF, 2018). In addition to an initial prostate biopsy, there are several indications for repeat prostate biopsy, as noted in Box 150.1.

Box 150.1

Commonly Cited Indications for Transrectal Ultrasonography Alone and Transrectal Ultrasonography With Initial and Follow-Up Prostate Biopsy

Transrectal Ultrasonography Without Prostate Biopsy

- Treatment planning volume measurements: brachytherapy, cryotherapy, benign prostatic hyperplasia therapy (e.g., transurethral microwave thermotherapy, radiofrequency ablation)
- Volume measurement during hormonal downsizing for external-beam radiation therapy or brachytherapy
- Placement of fiducial or radiofrequency markers for external-beam radiation therapy
- Evaluation of azoospermia (e.g., ejaculatory duct cysts, seminal vesicle cysts)
- Therapeutic aspiration or unroofing of prostatic cysts; drainage of prostatic

abscess

Initial Prostate Biopsy

- Initial diagnosis of prostate cancer based on informed decision making in an asymptomatic patient (based on PSA and patient-specific risk factors; see text)
- Suspicious digital rectal examination findings/prostate nodule (5%–30% cancer risk)
- To diagnose prostate cancer with symptoms suggestive of prostate cancer
- To diagnose prostate cancer with findings suggestive of metastatic disease (bone lesions and/or adenopathy)
- In the setting of prostate cancer detected on routine transurethral resection of the prostate performed for presumed benign disease

Repeat Prostate Biopsy

- Rising and/or persistently elevated PSA
- Atypical small acinar proliferation (40% cancer risk)
- Extensive (multiple biopsy sites) with PIN (20%–30% cancer risk) (*Note:* isolated high-grade PIN is no longer considered an indication for repeat biopsy)
- Positive urinary PCA3 or other newer genomic tests such as ConfirmMDx[a] methylation assay
- Suspicious lesion on prostate magnetic resonance imaging
- Differentiate local recurrence versus systemic disease with PSA recurrence after local ablative therapy

Follow-Up Prostate Biopsy

- Active surveillance follow-up protocol

PIN, prostatic intraepithelial neoplasia; *PSA*, prostate-specific antigen.

The use of newer molecular techniques such as urinary determination of PCA3 to identify men at risk for a positive biopsy finding is evolving. Several studies have suggested that PCA3 provides supplemental information in determining the need for repeat prostate biopsy (Gittelman et al., 2013). In the largest study of this urinary marker to date, the mean PCA3 was 27.2 and 52.5 for patients without and with cancer, respectively, suggesting this is a useful tool in identifying patients at risk for prostate cancer before initial biopsy (Chevli et al., 2014). The use of genomic markers for prostate cancer detection is a growing and rapidly evolving field, with increased awareness of applicability to improve the known poor specificity of PSA alone. (Cucchiara et al., 2018). There is also a growing awareness of inherited risk for prostate cancer, with implications for prostate cancer detection and biopsy (Giri et al., 2018).

Contraindications to Prostate Biopsy

Significant coagulopathy, severe immunosuppression, and acute prostatitis are all contraindications to prostate biopsy. With painful anorectal conditions or anal stenosis, prostate biopsy under general or regional anesthesia should be considered.

Preparing Patients for Biopsy

Patients should be informed of the risks and benefits of the procedure, and informed consent should be obtained. Herbal supplements also should be discontinued because many contain undeclared agents. Low-dose aspirin does not need to be discontinued (Giannarini et al., 2007). Anticoagulant therapy (e.g., warfarin, clopidogrel) should be stopped 7 to 10 days before prostate biopsy. The novel oral anticoagulants apixaban, dabigatran, and rivaroxaban are stopped 2 to 5 days before biopsy (Culkin et al., 2014). Rivaroxaban may increase stroke risk if stopped; therefore bridging with some other anticoagulant such as heparin is recommended. For those patients with underlying coagulopathy or on warfarin, prostatic biopsy should not be performed until the international normalized ratio has been corrected below 1.5 if the patient has low risk for a thromboembolic event. **For patients at increased risk for thromboembolic events (e.g., mechanical valves) on warfarin, bridging anticoagulation with unfractionated heparin or low-molecular-weight heparin is suggested.**

A small amount of urine in the bladder is useful before the biopsy. This helps facilitate the examination by demonstrating the prostatic bladder junction.

Antibiotic Prophylaxis

An increasing frequency of complications has been recently noted with most postbiopsy hospitalizations resulting from infectious causes (Loeb et al., 2013). This has placed a renewed focus on antibiotic prophylaxis and other strategies to reduce postbiopsy infectious complications. Unlike other lower urinary tract procedures, antimicrobial prophylaxis is recommended for all patients undergoing prostate biopsy, irrespective of risk factors. The 2014 updated latest AUA best practice policy recommended antibiotics for prostate biopsy including fluoroquinolones; first-, second-, and third-generation cephalosporins; and aminoglycoside (level of evidence, Ib) (AUA, 2014). The 2014 update added oral trimethoprim-sulfamethoxazole as a prophylactic agent, and when using intramuscular or intravenous aminoglycoside or aztreonam as an alternative agent, metronidazole or clindamycin is no longer required. The intramuscular route is acceptable for all recommended agents, and the oral route is recommended only for quinolones (Table 150.1). For patients at risk for developing endocarditis or infection of prosthetic joints, pacemakers, and automated implanted cardiac defibrillators, prophylaxis should consist of intravenous ampicillin (vancomycin, if penicillin-allergic) and gentamicin preoperatively, followed by 2 to 3 days of an oral fluoroquinolone. **After an FDA warning and label change in 2016 regarding fluoroquinolone toxicity (musculoskeletal concerns [tendinitis and tendon rupture], peripheral neuropathy, central nervous system side effects, or myasthenia gravis), the AUA recommended shortening the use of fluoroquinolone prophylaxis to a maximum of 24 hours.**

TABLE 150.1

American Urological Association 2014 Best Practice Policy Recommended Antibiotics for Routine Prostate Biopsy[a]

DRUG	DOSAGE
FLUOROQUINOLONES[b]	
Levofloxacin	500 mg PO single dose
Ciprofloxacin	500 mg PO q12h
Ofloxacin	400 mg PO q12h
AMINOGLYCOSIDES[c]	
Gentamicin	5 mg/kg IV single dose
Tobramycin	5 mg/kg IV single dose
Amikacin	15 mg/kg IV single dose
FIRST-GENERATION CEPHALOSPORINS	
Cephalexin	500 mg PO q6h
Cephradine	500 mg PO q6h
Cefadroxil	500 mg PO q12h
Cefazolin	1 g IV q8h
SECOND-GENERATION CEPHALOSPORINS	
Cefaclor	500 mg PO q8h
Cefprozil	500 mg PO q12h
Cefuroxime	500 mg PO q12h
Cefoxitin	1–2 g IV q6h
THIRD-GENERATION CEPHALOSPORINS	
Ceftizoxime	1 g IV q8h
Ceftazidime	1 g IV q12h
Ceftriaxone	1–2 g IV single dose
Cefotaxime	1 g IV q8h
ALTERNATIVE AGENTS	
Aztreonam	1–2 g IV q8h
Trimethoprim-sulfamethoxazole	1 double-strength tablet PO q12h

[a] The recommended duration of antimicrobial prophylaxis is 24 hours or less (level of evidence: Ib).

[b] Fluoroquinolones are associated with an increased risk for tendinitis and tendon rupture.

[c] Aztreonam can be substituted for aminoglycosides in patients with renal insufficiency.

IV, intravenously; *PO,* by mouth.

Modified from American Urological Association. Best practice policy statement on urologic surgery antimicrobial prophylaxis. 2014 update. Available at: https://www.auanet.org/guidelines/antimicrobial-prophylaxis-best-practice-statement.

A 2011 Cochrane review on prophylaxis for TRUS prostate biopsy demonstrated a reduction in bacteriuria, bacteremia, fever, urinary tract infection (UTI), and hospitalization with antibiotics compared with placebo or no treatment (Zani et al., 2011). There was no definitive evidence demonstrating superiority of a longer course or multiple doses compared with a shorter course or single any-dose protocols.

As a result of the increasing resistance patterns to fluoroquinolones, there has been recent interest in using individual culture data to guide antibiotic prophylaxis by using a rectal swab culture before biopsy (Taylor et al., 2012). The presence of fluoroquinolone-resistant organisms on a rectal swab culture has not always translated into clinical infection. In one multi-institutional study, rectal swab cultures immediately before biopsy in 136 men who received ciprofloxacin and gentamicin for prophylaxis had fluoroquinolone-resistant *Escherichia coli* in 22% of cultures (Liss et al., 2011). Only 5 (4%) patients had postbiopsy fever, and only 1 of them had a positive rectal screen for resistant *E. coli.* Although this result might have been prevented through targeted prophylaxis, the low overall complication rate raises questions about the cost-effectiveness of such a strategy. Additional studies are needed to define culture-directed therapy and compare its cost-effectiveness to empirical therapy based on local susceptibility patterns (Loeb, 2013). A risk-adjusted strategy for decreasing infectious complications after biopsy, including prospective monitoring of antibiotic resistance patterns, combination oral and intramuscular antibiotic administration, and selective use of prebiopsy rectal swab screening of high-risk patients appeared effective in a recent prospective study (Woldu et al., 2018).

Cleansing Enema

We routinely have patients self-administer a cleansing enema at home before biopsy. **This practice decreases the amount of feces in the rectum, thereby producing a superior acoustic window for prostate imaging.** The enema's effect on reducing infections is debatable. However, many clinicians may elect not to use an enema because this may allow more spontaneous performance of a prostate biopsy.

Analgesia

TRUS-guided infiltration anesthesia near the nerve bundles with local

anesthetic can provide excellent pain control (Berger et al., 2003; Trucchi et al., 2005). A local prostatic block is achieved using 1% to 2% lidocaine, a long spinal needle (7-inch, 22-gauge), and TRUS guidance along the biopsy channel of the transducer. Multiple variations exist for the infiltration of local anesthetic for transrectal biopsy (Ismail and Gomella, 2013). We found that injecting 5 mL of lidocaine at the level of the SVs near the bladder base at the hyperechoic fat pad that demarcates the junction of the SVs and the prostate bilaterally produces an excellent block. Other approaches include infiltration of 10 mL starting at the junction of the SVs and infiltrating along the lateral aspect of the prostate from base to apex. **Direct infiltration into the prostate (intraprostatic injection) can augment the anesthetic benefit seen with periprostatic injection** (Cam et al., 2008). Saturation biopsy schemes may require up to 22 mL of 1% lidocaine. Caution is needed, however, to avoid direct intravascular injection because of the risk for systemic lidocaine absorption. Intrarectal (topical) instillation of a local anesthetic is inferior to periprostatic infiltration for pain control during biopsy (Heidenreich et al., 2014). However, topical lidocaine may be useful when the patient expresses tenderness to probe insertion. **Local anesthesia for transperineal biopsies also should include infiltration of the skin and subcutaneous tissues of the perineum initially.** Ultrasound guidance then may be employed to aid infiltration of deeper tissues along the anticipated tracts of the biopsy needle.

Patient Positioning

Patients are usually placed in the left lateral decubitus position with knees and hips flexed 90 degrees. An armboard attached parallel to the table and a pillow between the knees help maintain this position. The buttocks should be flush with the end of the table to allow manipulation of the probe and biopsy gun without obstruction. If necessary, the right lateral decubitus or lithotomy position can be used. **The lithotomy position is used by some clinicians and is preferred for transperineal biopsies, brachytherapy treatment planning, vascular examination of the prostate with color or power Doppler or contrast enhancement (for which gravity will alter or distort vascular patterns), or placement of fiducial gold markers for external-beam therapy** (Dehnad et al., 2003; Halpern et al., 2002).

Transrectal Prostate Biopsy Techniques

An initial digital rectal examination should be performed to evaluate for any prostate nodularity or anal pathologic processes. The prostate volume is determined, and imaging of the prostate in both the transverse and sagittal planes is begun. The examination usually starts at the base of the gland and extends to the apex. Most modern ultrasound units are automatically set for optimal prostate viewing, and the TRUS gray-scale examination of the prostate is conducted as described earlier, noting the location and characteristics of any lesions (i.e., hypoechoic, hyperechoic, calcifications, contour abnormalities, cystic structures).

A spring-driven 18-gauge needle core biopsy device or biopsy gun that can be passed through the needle guide attached to the ultrasound probe is most often used. Most ultrasound units provide best visualization of the biopsy needle path in the sagittal plane. Images are typically superimposed with a ruled puncture path that corresponds to the needle guide of the TRUS unit. The biopsy gun advances the needle 0.5 cm and samples the subsequent 1.5 cm of tissue with the tip extending 0.5 cm beyond the area sampled (Kaye, 1989). Therefore, when sampling the PZ, the needle tip may be placed 0.5 cm posterior to the prostate capsule before firing; advancing the needle to or through the capsule can result in sampling of more anterior tissue, missing the most common location of cancers. Avoiding adjustment of the probe position while the biopsy needle is in contact with the rectal surface and applying pressure with the probe to compress the rectal mucosa before biopsy can minimize rectal bleeding. Pressing the probe against the rectum also minimizes the discomfort of the biopsy needle traversing the rectal mucosa, similar to pulling the skin tight to minimize the discomfort of phlebotomy.

The biopsy sample is typically placed in 10% formalin or per local protocol. An AUA white paper recently outlined the recommended processing of prostate biopsy samples, and the review did not provide compelling evidence that individual site–specific labeling of cores benefits clinical decision making regarding the management of prostate cancer (Bjurlin et al., 2013). The paper recommends packaging no more than two cores in each jar to avoid reduction of the cancer detection rate through inadequate tissue sampling.

Sextant Biopsy

The original sextant biopsy scheme (one core from the base, mid, and apex bilaterally) significantly improved cancer detection over digitally directed biopsy of palpable nodules and ultrasound-guided biopsy of specific

hypoechoic lesions (Hodge et al., 1989). Taken in the parasagittal plane, these cores sampled a portion of the PZ but also included a significant amount of tissue from the TZ. Subsequent studies of radical prostatectomy specimens demonstrated that the vast majority of adenocarcinomas arise in the posterolateral PZ (McNeal et al., 1988), thus explaining some of the false-negative results of standard sextant biopsy (Eskew et al., 1997).

Extended-Core Biopsy Techniques

Modifications to the standard sextant biopsy scheme initially focused on the importance of laterally directed cores (Terris et al., 1992). Numerous studies have shown improved cancer detection rates by incorporating additional laterally directed cores into the standard systematic sextant technique. **At present, six cores are considered inadequate for routine prostate biopsy for cancer detection.** Fig. 150.5 depicts the originally proposed sextant technique and several common extended-core biopsy strategies.

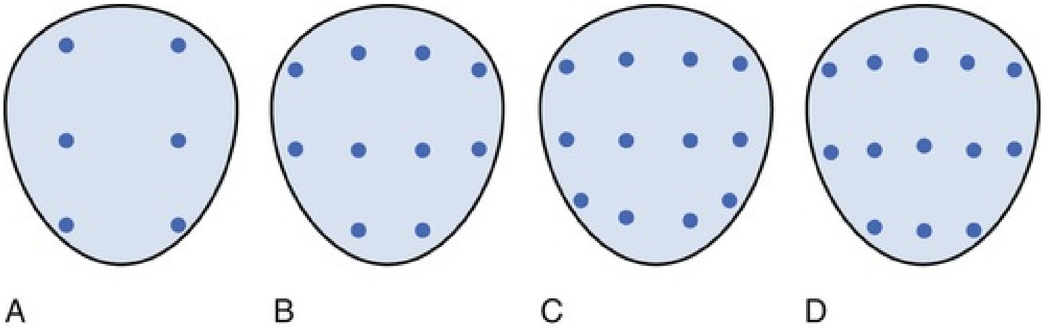

FIG. 150.5 Various reported systematic biopsy schemes. Base is at the top of the figure, apex is at bottom. (A) Sextant biopsy scheme originally proposed by Hodge et al. (1989). (B) The 10-core biopsy (Presti et al., 2000). (C) The 12-core, or double-sextant, biopsy. This is the currently recommended sequence endorsed by the American Urological Association (Bjurlin et al., 2013). (D) The 13-core, 5-region biopsy (Eskew et al., 1997).

Today the extended 12-core systematic biopsy that incorporates apical and far-lateral cores in the template distribution allows maximal cancer detection and avoidance of a repeat biopsy while minimizing the detection of insignificant prostate cancers. This approach has been endorsed in a recent AUA white paper (Bjurlin et al., 2013, 2014). Although increasing the cores from 6 to 12 results in a significant increase in cancer detection rate, increasing the number of cores to 18 or 21 (often termed *saturation biopsy*) as an initial biopsy strategy does not appear to result in a similar increase. However, a series of men from the Cleveland Clinic whose initial biopsy was by a transrectal saturation technique were less likely to have cancer identified during repeat biopsy. Further, if prostate cancer was diagnosed after negative initial saturation biopsy, it was much more likely to be clinically insignificant (Li et al., 2014). Their findings suggest that saturation biopsy may be less likely to miss clinically significant cancer during initial prostate biopsy. At present, saturation biopsy is more likely to be considered in the setting of a prior negative biopsy (see later discussion).

The TZ and SVs are not routinely sampled because these regions have been shown to have consistently low yields for cancer detection at initial biopsy (Epstein et al., 1997), but TZ and anteriorly directed biopsies may occasionally prove necessary to diagnose prostate cancer in those patients with persistently elevated PSA levels and prior negative biopsies (Mazal et al., 2001). **However, there may be a limited role for TZ sampling during the initial biopsy in men with gland size of more than 50 mL, with an additional yield of 15% cancer detection in these larger prostates** (Chang et al., 1998). Today, magnetic resonance imaging (MRI) is often used to detect and guide biopsies of these anterior tumors that may escape standard TRUS prostate biopsy (Volkin et al., 2014). SV biopsy is not routinely performed unless there is a palpable abnormality, with some authors recommending SV biopsy when the PSA value is greater than 30 or if brachytherapy is being considered (Gohji et al., 1995).

Repeat and Saturation Prostate Biopsy

The dilemma of a patient who has had one or more negative prostate biopsies yet continues to have an elevated PSA value or abnormal digital rectal examination of concern for prostate cancer is a common clinical scenario. Often these patients have undergone multiple biopsies despite the well-documented decline in cancer detection with each successive biopsy (Djavan et al., 2003). Keetch et al. (1994) reported an initial positive biopsy rate of 34% in 1136 men from their PSA-based prostate cancer screening program. Cancer detection rates then fell to 19%, 8%, and 7% on biopsy 2, 3, and 4, respectively. These findings were confirmed by results from an initial ERSPC series. **In this cohort of 1051 men with PSA values between 4.0 and 10.0 ng/mL, the initial cancer detection rate with sextant biopsy was 22%. Positive cores were then found in only 10%, 5%, and 4% of patients on subsequent biopsies 2, 3, and 4, respectively** (Djavan et al., 2001a). In a contemporary follow-up from the same ERSPC study, positive predictive values (PPVs) for men without previous biopsy remained equal throughout the three subsequent screenings (25.5%, 22.3%, and 24.8%, respectively) (Bokhorst et al., 2012). Conversely, PPVs for men with a previous negative biopsy result dropped significantly (12.0% and 15.2% at the second and third screening, respectively). In men with and without previous biopsy, the percentage of aggressive prostate cancers (clinical stage >T2b, Gleason score ≥7) decreased after the first round of screening from 44.4% to 23.8% in the second round and 18.6% in the third. Repeat biopsies accounted for 24.6% of all biopsies, but yielded only 8.6% of all aggressive cancers.

The diminishing returns coupled with improved cancer detection rates on initial biopsy with extended-core protocols have led some researchers to examine saturation biopsy techniques (i.e., >12-core biopsy) in this difficult subset of patients with negative previous biopsy results. In a study of 57 men with an average of two prior negative sextant biopsies, a cancer detection rate of 30% was obtained, with an average of 22.5 cores per patient (Borboroglu et al., 2000). Similar protocols from the Mayo Clinic (Stewart et al., 2001) and Toronto (Fleshner and Klotz, 2002) demonstrated improved cancer detection rates. **A drawback to these techniques is that additional anesthetic requirements often require these saturation biopsies to be performed in a hospital setting.** More recent reports question the benefit of a follow-up saturation biopsy scheme, considering the attendant increased cost and potential morbidity. In a reassessment of their previous work on saturation biopsy, investigators at the Mayo Clinic performed a large prospective study of standard systematic and saturation biopsy techniques and did not find a significant increase in prostate cancer detection (Ashley et al., 2008).

The use of a second prostate biopsy in all cases of a negative finding on initial biopsy appears justified if there are concerns about undetected cancer. Third and fourth repeat biopsies, however, should be obtained only in selected patients with high suspicion for cancer and/or poor prognostic factors on the first or second biopsy (Djavan et al., 2005). **When performing repeat biopsy, attention should be placed on the apex, which may not be adequately sampled by the TRUS biopsy approach.**

The role of additional modalities continues to evolve in the setting of repeat biopsy. Techniques such as contrast-enhanced TRUS (CE-TRUS) and MRI-targeted approaches discussed later in this chapter will have an impact on the approach to negative biopsy in the future (Halpern et al., 2005; Volkin et al., 2014). The use of newer molecular and genomic assays also will have an impact on the decision making in the future in the setting of a negative prostate biopsy

(Gittelman et al., 2013; Gomella and Amirian, 2015; Partin et al., 2014).

Transperineal Prostate Biopsy

Transperineal biopsy offers an approach to the prostate in those patients lacking a rectum (e.g., surgical extirpation, congenital anomaly). The potential for reduced infectious and other complication rates and improved identification of apical tumors are now considered benefits to the transperineal biopsy technique (Chang et al., 2013; Roberts et al., 2017). The main trade-off appears to be the need for more extensive anesthesia when using the perineum to approach the prostate, and the inferior visualization of the prostate, which reduces precision of the systematic targeting process.

The patient is positioned in the dorsal lithotomy position with the perineum shaved and prepped as for a sterile surgical procedure. An end-fire ultrasound transducer is used. Despite significant limitations in visualization via this technique compared with TRUS, the prostate can and should be imaged in both the coronal and sagittal planes with calculation of the gland volume. Via the transperineal window, focal PZ hypoechoic lesions are difficult to visualize, as are the SVs. The urethra will appear as a hypoechoic midline structure and may be readily identified by following the corpus spongiosum proximally from the base of the penis. Once the boundaries of the gland have been clearly delineated in the coronal plane, a minimum of six cores should be taken, three from either side of midline.

The diagnostic yield of transperineal ultrasound-guided prostate biopsy was compared with that of TRUS-guided biopsy in a routine biopsy setting (Vis et al., 2000). By using radical prostatectomy specimens with TRUS biopsy–detected prostate cancer, simulated transperineal biopsies were performed and transrectal biopsies were repeated. Significantly, 82.5% of the known tumors were detected with the longitudinal transperineal approach versus 72.5% of cancer detection with repeat transrectal biopsy. The authors postulate that the longitudinal orientation of their cores allows more efficient sampling of the PZ, thereby improving cancer detection. These results, however, assume appropriate systematic positioning of transperineal biopsy cores; unfortunately, freehand transperineal targeting of biopsy cores is often limited by technical factors.

Using a template for the transperineal approach in the repeat biopsy setting, Pinkstaff et al. (2005) obtained a mean of 21.2 cores (range, 12 to 41) in 210 men. The transperineal approach enhanced identification of TZ cancers not detected by previous transrectal prostate biopsy in high-risk patients. However, in a Japanese randomized trial comparing transrectal and transperineal techniques for initial prostate biopsy, the cancer detection rate was similar for both, with higher complications noted in the transperineal approach (Hara et al., 2008). Therefore the authors concluded that transrectal prostate biopsy should be the preferred technique for initial prostate biopsy. An increased rate of urinary retention is noted for the transperineal approach, especially in the saturation biopsy setting (Moran et al., 2006). More recently, numerous benefits have been cited: possible improved cancer detection rates, improved anterior and apical sampling, reduced false-negative results, and reduced risk for underestimating disease volume and grade. **The increasing incidence of antimicrobial resistance and patients with diabetes mellitus who are at high risk for sepsis also favors transperineal biopsy as a sterile alternative to standard TRUS-guided biopsy** (Chang et al., 2013; Roberts et al., 2017). The detection rate of anterior zone prostate cancer in patients undergoing initial and repeat transperineal prostate biopsy is increased by 10% in another series (Pepe et al., 2014).

The technique of three-dimensional transperineal mapping biopsy has been reported (Barqawi et al., 2011). This uses a transperineal brachytherapy template and can include over 50 mapping biopsy cores based on the size of the gland, far more than obtained with saturation biopsy. It may provide additional information and identify higher-risk disease in men thought to have low-risk disease on standard 10- to 12-core TRUS biopsy. Further investigations are needed to establish the utility of this approach.

Combining a transperineal biopsy strategy with MRI-targeted biopsies in the outpatient setting under local anesthesia offers several potential advantages, including lower sepsis and better detection of anterior and apical tumors (Pepe et al., 2017; Zhang et al., 2017). Commercial systems to incorporate transperineal biopsy with an MRI-targeted biopsy approach are being developed to gain the advantage of a transperineal approach in an outpatient setting (Kosarek et al., 2018). As clinical experience grows with these biopsy platforms, the incremental improvement in biopsy accuracy and decreased sepsis will require careful examination.

Transurethral Prostate Biopsy

Transurethral resection biopsy was once advocated for the diagnosis of TZ cancers or after negative TRUS sampling. In contemporary series, solitary TZ cancers, without concomitant PZ tumors, are estimated to occur in less than 5% of patients with prostate cancer (Pelzer et al., 2005). **With improved TRUS techniques including local anesthesia, the TZ can be adequately sampled, and the value of transurethral biopsy has been questioned for the vast majority of patients** (Bratt, 2006). In addition, MRI has shown utility in the identification of TZ and anterior prostate cancers and is particularly effective when used in a TRUS/MRI fusion biopsy system, further limiting the utility of the transurethral biopsy (Volkin et al., 2014).

Risks and Complications of Prostate Biopsy

Although generally considered a safe procedure, TRUS prostate biopsy can be associated with complications. The incidence of serious complications requiring hospitalization is relatively low (<1%). In a Canadian study of more than 41,000 men with negative biopsy results, the 30-day hospital admission rate after prostate biopsy increased from 1.0% in 1996 to 4.1% in 2010 (Nam et al., 2013). The majority of hospital admissions (72%) were related to bacterial infections. An overview of common complications include hematospermia, hematuria, rectal bleeding, prostatitis, fever greater than 101.3°F, epididymitis, urinary retention, and other complications requiring hospitalization (Heidenreich et al., 2014). Large screening series such as the PLCO and ERSPC show that prostate biopsy is not associated with excess mortality, and the overall rate of infectious complications is less than 1% (Pinsky et al., 2014). This low overall absolute risk for serious biopsy-related complications suggests that a fear of complications alone should not deter healthy men with a long life expectancy from pursuing early prostate cancer detection.

Postbiopsy Infections

Infection is the most common complication of prostate biopsy, with fluoroquinolone-resistant *E. coli* having a prominent role. Reported rates of infectious complications range from 0.1% to 7.0%, and sepsis rates range from 0.3% to 3.1% depending on antibiotic prophylaxis regimens (Liss et al., 2017). Most infectious complications after TRUS biopsy are limited to symptomatic UTI and low-grade febrile illness, which can be readily treated with oral or intravenous antibiotics; however, an increasing incidence of hospitalizations and fatal sepsis after prostate biopsy are being reported (Wagenlehner et al., 2014).

The contemporary risk for hospitalization for infectious complications ranges from 0.6% to 4.1%, with the reported incidence of UTI from 2% and 6% (Bjurlin et al., 2014; Nam et al., 2013). **Although hospitalizations for sepsis are increasing after prostate biopsy, data suggest that the mortality in this group was not excessive when compared with that of other similar systemic infections** (Carter et al., 2013; Loeb, 2013; Loeb et al., 2013). Sepsis is the clinical syndrome characterized by a systemic inflammatory reaction to an infectious process; the symptoms are nonspecific and may include fever, hypothermia, tachypnea, tachycardia, altered mental status, and hypotension (AUA/SUNA, 2012). Any patient who presents with a fever after a prostate biopsy should be assessed for the presence of sepsis. Septic shock refers to acute circulatory failure (hypotension) that persists despite adequate fluid resuscitation.

A main factor for severe infection seems to be the presence of fluoroquinolone-resistant fecal bacteria, likely related to the widespread use of these agents in health care settings, and in sources of the food supply (Heuer et al., 2009). The use of targeted prophylaxis after rectal flora swabbing and culture has been shown to have some utility compared with empirical antibiotic prophylaxis in some series. Various bowel preparations are under investigation, but none have been shown to significantly reduce infection rates. As discussed earlier, transperineal prostate biopsy is currently being evaluated to reduce infections, with limited data supporting this approach at present (Grummet et al., 2014).

Organisms reported to result in sepsis are predominantly *E. coli*, with high rates of resistance to fluoroquinolones, trimethoprim-sulfamethoxazole, and ampicillin. However, all isolates in this series were susceptible to second- and third-generation cephalosporins, amikacin, and carbapenems (e.g., imipenem, meropenem) (Loeb, 2013). **Risk factors for prostate biopsy–related infection include: nonwhite race, increased number of comorbidities, diabetes mellitus, prostate enlargement, foreign travel, and recent antibiotic use.** Another risk factor is the number of previous biopsies. The number of previous prostate biopsies was significantly associated with an increased risk for infectious complications in men on an active surveillance protocol (Ehdaie et al., 2014). **Familiarity with local antibiotic resistance patterns can aid in rapid treatment of symptomatic infection after prostate biopsy.**

Bleeding

Even with normal coagulation parameters, bleeding is the most common complication seen after prostate biopsy. Prostate biopsy is considered to pose an intermediate risk for bleeding (Naspro et al., 2013). As noted, any potential medications that can alter coagulation parameters, including herbal remedies, should be held for 5 to 7 days before biopsy and those on warfarin managed as noted. Two large European screening programs noted hematuria in 23% to 63% of men after sextant biopsy, with clot retention developing in 0.7% (Djavan et al., 2001b; Raaijmakers et al., 2002). Rectal bleeding is common and seen in 2.1% to 21.7% of patients (Djavan et al., 2001b; Enlund and Varenhorst, 1997). **Rectal bleeding is typically minor and readily controlled with direct pressure by the ultrasound probe or digitally; persistent brisk blood loss per rectum may require more aggressive intervention for control.** Additional measures include rectal tamponade with an inflated condom, anoscopy/colonoscopy with injection of epinephrine and polidocanol or use of sclerotherapeutic agents, angiography with embolization, transrectal exploration, and suturing (AUA/SUNA, 2012).

Hematospermia, commonly seen after biopsy, is of minimal clinical importance but can cause significant anxiety if not discussed at the time of biopsy; 9.8% to 50.4% of men experience some blood in their ejaculate (Djavan et al., 2001b; Raaijmakers et al., 2002). In one study, the mean duration of hemospermia was 4 (±1.4) weeks, with the number of ejaculations before resolution at six (±5.6). No factors predicted the duration of hemospermia (Abdelkhalek et al., 2013).

Other Complications

Excessive anxiety and discomfort from the endorectal probe may produce a moderate or severe vasovagal response in 1.4% to 5.3% of patients (Djavan et al., 2001b; Rodriguez and Terris, 1998) and may require termination of the procedure. Placing the patient in the Trendelenburg position and use of intravenous hydration usually resolve these symptoms, with further intervention as clinically indicated.

Acute urinary retention requiring temporary catheterization develops in 0.2% to 0.4% of patients after TRUS biopsy (Enlund and Varenhorst, 1997; Raaijmakers et al., 2002). Men with significantly enlarged glands and those with significant lower urinary tract symptoms, such as those with a high International Prostate Symptoms Score (IPSS), are more prone to develop retention (Rodriguez and Terris, 1998; Raaijmakers et al., 2002). Any prostate biopsy may increase the IPSS, but this appears to be transient.

The effects of prostate biopsy on erectile dysfunction have been incompletely characterized. Very early studies suggested that erectile dysfunction after TRUS biopsy was caused by damage to the neurovascular bundles (Zisman et al., 2001). Since that time the studies have been conflicting, with a more recent study suggesting erectile dysfunction is more pronounced in men who had a diagnosis of prostate cancer than in those who were cancer free (Helfand et al., 2013).

Advanced and Investigational Techniques for Prostate Biopsy

Color and Power Doppler Transrectal Ultrasonography

Color Doppler imaging is based on the frequency shift in the reflected sound waves from the frequency of insonation and thus depicts the velocity of blood flow in a directionally dependent manner (Fig. 150.6A). **Color assignment is based on the direction of blood flow related to the orientation of the transducer receiving the signal; by accepted convention in most institutions, flow toward the transducer is depicted in shades of red and flow away in shades of blue; the color is not specific for arterial or venous flow.** Power Doppler imaging (also known as *enhanced color Doppler, color amplitude imaging*, or *color angiography*) uses amplitude shift to detect flow in a velocity and directionally independent manner (Bude and Rubin, 1996) (see Fig. 150.6B). The advantages of power Doppler imaging are its ability to detect slower flow and less reliance on the Doppler angle, making it more suitable for detection of prostate cancer neovascularity. Although power Doppler imaging offers improved sensitivity to small amounts of flow, neither modality has yet proved itself superior to the other for cancer detection.

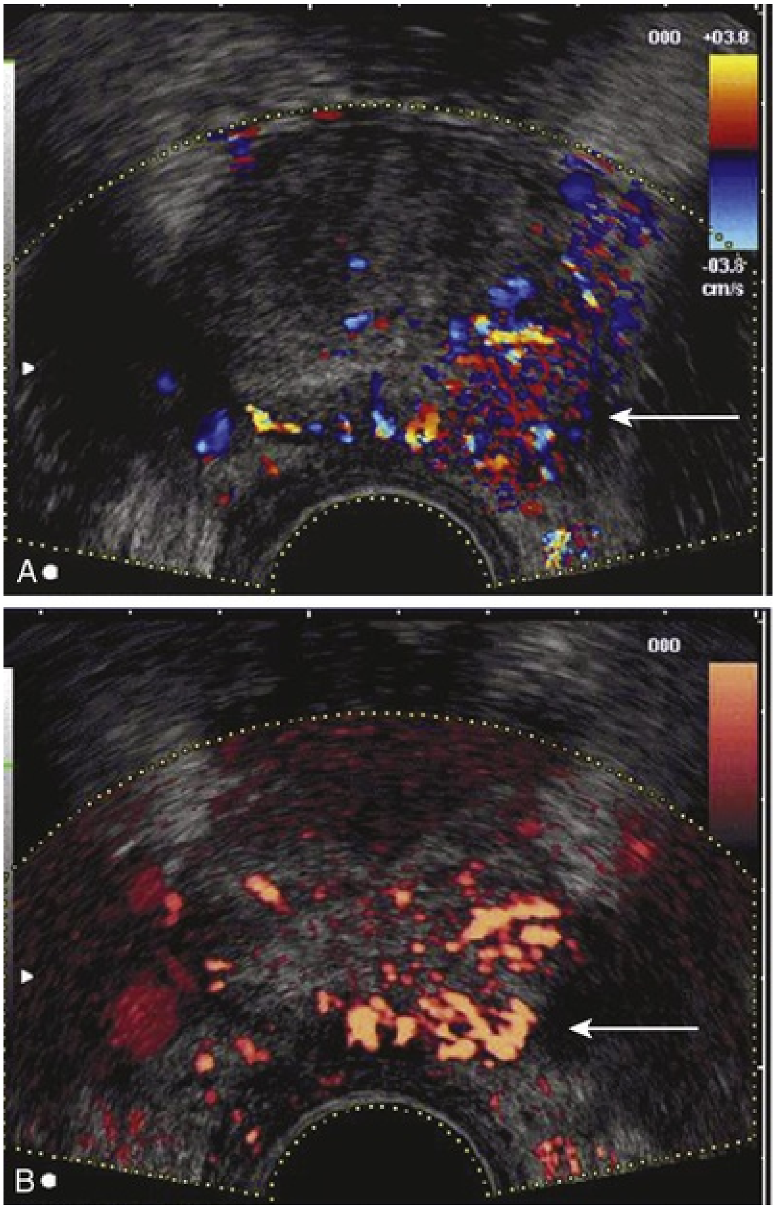

FIG. 150.6 Color Doppler (A) transrectal ultrasonography (TRUS) and power Doppler (B) TRUS identify a Gleason 4 + 4 = 8 adenocarcinoma *(arrows)* in the left mid-gland.

One series found color Doppler sensitivity and specificity of 14.6% and 93.9%, respectively, to identify cancer (Halpern and Strup, 2000). Whereas Doppler modes showed an improved diagnosis versus gray-scale TRUS, 45% of cancers still went unidentified by any sonographic modality. Others have shown increased cancer detection rates using Doppler-targeted biopsy strategies, but none is sufficiently accurate to replace systematic biopsy (Halpern et al., 2002). Enhancements in the technical aspects of color Doppler TRUS, including the use of contrast agents (see later discussion), may provide the necessary improvements to specifically identify cancer sites in the future.

Multiple studies have shown that angioneogenesis and the resultant increase in microvessel density that occurs within foci of prostatic adenocarcinoma correlates with the presence of metastases (Weidner et al., 1993), stage of disease (Bostwick et al., 1996), and disease-specific survival (Borre et al., 1998; Lissbrant et al., 1997). Interest in using color and power Doppler TRUS to aid in prostate cancer detection stems from studies of radical prostatectomy specimens demonstrating that foci of adenocarcinoma possess an increased density of microvessels compared with surrounding normal parenchyma (Bigler et al., 1993).

Patients with detectable color Doppler flow within their dominant tumor at the time of TRUS-guided biopsy are at a 10-fold increased risk for PSA recurrence after radical retropubic prostatectomy (Ismail et al., 1997). The presence of increased flow was also associated with higher Gleason grade, increased incidence of SV invasion, and a lower biochemical disease-free (bNED) survival rate versus subjects without increased flow on preoperative TRUS (Ismail et al., 1997). Other investigators also have shown the association of power Doppler flow signals as an indicator of microvessel density with higher Gleason score and have suggested a correlation with outcome (Wilson et al., 2004).

Current unenhanced Doppler modalities are not able to identify the microvessels of prostate cancer, which are typically 10 to 15 microns in diameter. The flow signals associated with malignant foci detected by unenhanced color and power Doppler imaging are caused by detection of larger feeding vessels (Ismail and Gomella, 2001). Intravenous microbubble ultrasound contrast agents, similar to those currently approved and used in echocardiography, have been infused systemically during gray-scale and TRUS Doppler imaging to amplify flow signals within the microvasculature of prostate tumors, allowing selective visualization of malignant foci in clinical trials (Halpern et al., 2000; Ismail and Gomella, 2001). **These intravenous “bubble” contrast agents are constructed with air or higher-molecular-weight gas agents encapsulated (albumin or polymer hard shell, lipid, or surfactant coated) for longevity and are generally 1 to 10 microns in diameter.**

Using CE-TRUS for prospective prostate cancer detection, Halpern et al. (2001) demonstrated an increase in sensitivity from 38% to 65% versus baseline unenhanced imaging, without significantly altering specificity. Subsequent studies by our group and others have improved sonographic detection of malignant foci using CE-TRUS and targeted biopsy of enhancing lesions (Kundavaram et al., 2012). In a multi-institutional trial involving several European centers, CE-TRUS has been recommended for routine care in prostate biopsy (Wink et al., 2008). Imaging using microbubble contrast agents combined with three-dimensional image reconstruction of enhanced power Doppler images also demonstrated increased diagnostic accuracy (Unal et al., 2000) (Fig. 150.7). **Flash-replenishment imaging, a software modification, gives better visualization of small neovessels, down to the capillary level, for the detection of prostate cancer** (Linden et al., 2007). Flash replenishment imaging uses a combination of high-power flash pulses to destroy contrast microbubbles, followed by low-power pulses to demonstrate contrast replenishment. A composite image is constructed depicting the vascular architecture through maximum intensity capture of temporal data in consecutive low-power images and can be used for real-time targeted transrectal biopsy of areas of increased or abnormal vascularity. Using this technique, we have demonstrated much finer vascular detail for targeting biopsy, and targeted biopsy cores were significantly more likely to be cancerous than random systematic biopsy cores (Linden et al., 2007). Future developments in these and other imaging modalities that can selectively visualize prostate cancers based on the presence of angioneogenesis may ultimately allow more accurate localization of the sites of cancer.

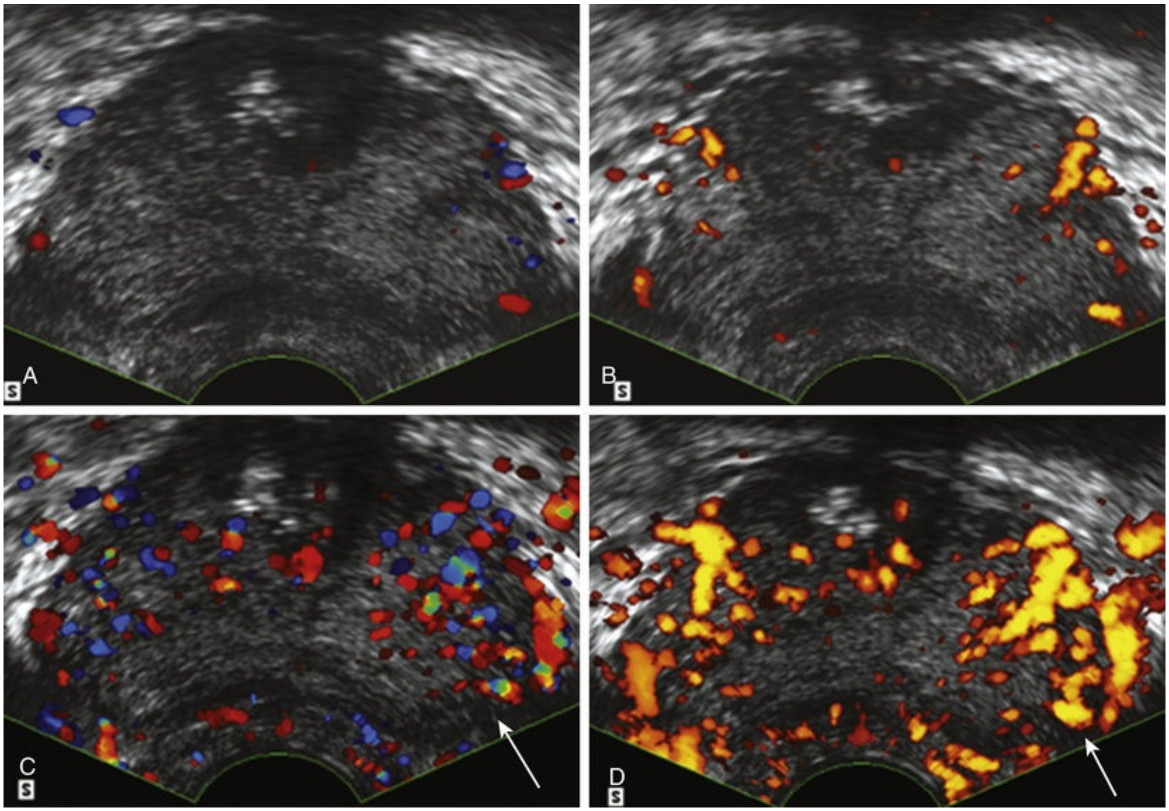

FIG. 150.7 Unenhanced color (A) transrectal ultrasonography (TRUS) and power Doppler (B) TRUS fail to detect evidence of an underlying malignancy. After infusion of a microbubble contrast agent, color (C) TRUS and power Doppler (D) TRUS demonstrate an area of increased flow in the left mid-gland that proved to be a Gleason 3 + 4 = 7 adenocarcinoma on targeted biopsy *(arrows).*

The technique of elastography may prove superior to color Doppler imaging in identification of malignant areas in the prostate (Nelson et al., 2007; Sumura et al., 2007). Early studies with elastography employed real-time sonographic imaging of the prostate at baseline, and under varying degrees of compression to add information about stiffness of the prostate tissue (Fig. 150.8). Through computerized calculations, differences in displacement between ultrasonic images from baseline and during compression may be visualized, and regions with decreased tissue elasticity (stiffness) may be suggestive of malignancy. More recent studies use the ultrasound beam itself to compress tissues, or rely on the velocity of shear waves to indicate the relative stiffness of underlying tissues; these newer techniques are independent of interuser variations related to the pressure applied during the examination. In a preliminary study of 404 cases with 151 cases positive for prostate cancer, the malignancy was found in 127 patients (84.1%) with real-time elastography directing the biopsy (Konig et al., 2005). Real-time elastography-targeted biopsy is an evolving method for increasing prostate cancer detection rates. Real-time elastography-targeted biopsies missed cancer in a high proportion of patients in one series of over 1000 men (Salomon and Schiffmann, 2014; Salomon et al., 2014). Another prospective study of shear wave elastography in 212 men undergoing prostatectomy who had prostate stiffness examined with shear wave elastography preoperatively and compared with final surgical pathology demonstrated differentiation of benign and malignant areas and increasing tissue stiffness with higher Gleason score (Wei et al., 2018). **With the conflicting data available at this time, elastography at present should be considered an additional technology to complement but not replace random biopsies** (Salomon et al., 2014).

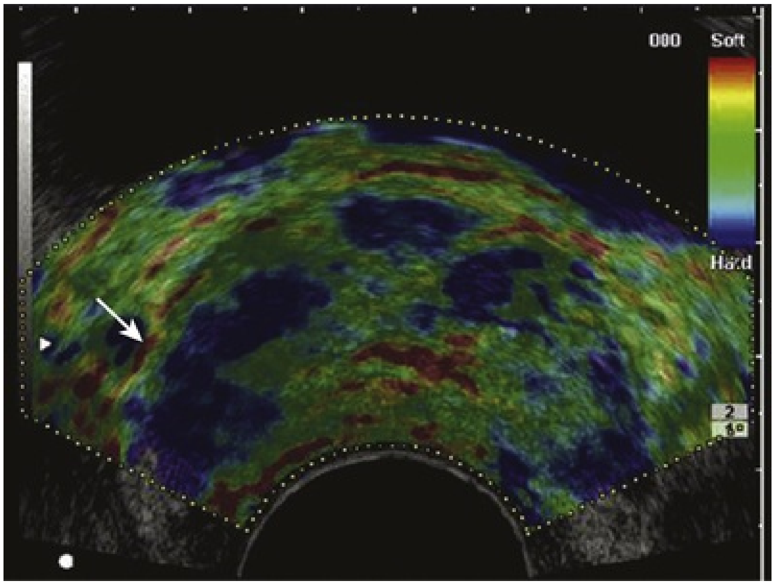

FIG. 150.8 Elastography demonstrates an area of decreased compliance in the right base consistent with an underlying malignancy *(blue near arrow).* Note color scale in upper right corner indicating relative tissue “firmness.” Targeted biopsy of this region revealed a Gleason 4 + 4 = 8 adenocarcinoma.

Other Newer and Investigational Imaging and Biopsy Techniques

Prostate HistoScanning (Advanced Medical Diagnostics, Waterloo, Belgium) is a proprietary tissue characterization technology reported to differentiate, characterize, and visualize prostate tissue, based on the analysis of backscattered ultrasound. It is an evolving technology, and a recent study of 105 patients suggested that the system could not reliably identify and characterize prostate cancer in a routine clinical setting (Javed et al., 2014). A more recent prospective study evaluating HistoScanning with mpMRI in men scheduled for radical prostatectomy also demonstrated inferior diagnostic accuracy as compared with mpMRI (Orczyk et al., 2016). This also calls into question the clinical impact of HistoScanning for prostate cancer biopsy.

Multiparametric Prostate Ultrasonography

Analogous to prostate MRI examined with multiple parameters, the concept of multiparameter prostate ultrasound evaluation is gaining enthusiasm as an alternative and/or complement to MRI. Parameters to evaluate prostate vascularity, including color and power Doppler and contrast enhancement, and assessment of tissue stiffness with elastographic parameters, can augment standard gray-scale ultrasonography for the accurate diagnosis of prostate cancer (Grey and Ahmed, 2016; Postema et al., 2015a, 2015b).

Multiparametric Magnetic Resonance Imaging of the Prostate

Improvements in the design and application of mpMRI have increased the ability to identify and localize prostate cancer. **Functional MRI parameters such as dynamic contrast enhancement and diffusion-weighted imaging alone or in combination have improved prostate cancer detection** (Turkbey and Choyke, 2012). The AUA created a Policy Statement on the use of mpMRI in the diagnosis, staging, and management of prostate cancer, and noted the rapid evolution of mpMRI in the management of prostate cancer (Fulgham et al., 2017). However, the diagnosis and histopathologic grading of prostate cancer still requires tissue for diagnosis. Although theoretically appealing, significant technical difficulties exist in performing real-time MRI-directed prostate biopsies. At the present time, there are three evolving techniques that combine MRI guidance for targeted prostate biopsies, namely direct “in-bore” MRI, cognitive fusion, and MRI/ultrasound fusion via software-based image coregistration (Logan et al., 2014).

The Prostate Image Reporting and Data System (PIRADS) categorization represents a consensus opinion to allow the systematic evaluation of lesions detected on mpMRI to estimate their potential risk for prostate cancer. Initially proposed by the European Society of Urogenital Radiology (ESUR) in 2012 (version 1), these guidelines helped standardize the interpretation and reporting of mpMRI prostate scans (Barentsz et al., 2012). A more recent update (version 2 or PIRADS v2) was compiled by the American College of Radiology (ACR), the ESUR, and the AdMeTech Foundation in 2015 and published in 2016 (Weinreb, et al., 2016). This update includes clinical and technical considerations for mpMRI and a standardized lexicon for reporting the results of these examinations. In PI-RADS v2, the scoring remains a Likert scale from 1 to 5, with higher numbers indicative of increased risk for a clinically significant malignancy (Box 150.2), defined as tumors with Gleason score greater than or equal to 7 and a volume greater than 0.5 cm^3 or extraprostatic extension (EPE). The peripheral zone and transitional/central zone are scored separately, with both reported in the examination synoptic. The scheme for assigning PI-RADS categories is dependent on multiple parameters of the MRI examination, including T2-weighted imaging (T2WI), dynamic contrast-enhanced (DCE) imaging, and diffusion-weighted imaging (DWI). Using this system, each suspicious lesion is scored from 1 to 5 for T2WI and DWI, and the DCE is classified as positive (presence of contrast enhancement) or negative (no contrast enhancement) to give a final PI-RADS score as shown in Tables 150.2 and 150.3. **Size and appearance are also an important aspect of distinguishing lesions seen either in the PZ or TZ, in addition to the MRI parameters (T2WI, DCE, DWI). Lesions that are greater than 1.5 cm on T2WI or with high suspicion of EPE are assigned as a PI-RADS 5 lesion** (Weinreb, et al., 2016). Recent prospective validation studies from Germany and the Netherlands confirmed the ability of the PI-RADS v2 system to detect prostate cancer on biopsy. Hofbauer et al. (2018) reported on 704 men undergoing MRI fusion biopsy, demonstrating a cancer detection rate for PI-RADS 3, 4, and 5 lesions of 39%, 72%, and 91%, respectively. When detection rates were calculated for only clinically significant tumors, the positive predictive rates for PI-RADS 3, 4, and 5 lesions were 23%, 49%, and 77%, respectively. At Nijmegen, similar results were reported in 1057 men, with an overall cancer detection rate of 35%, 60%, and 91% for PI-RADS 3, 4, and 5 lesions, respectively, and a clinically significant cancer detection rate of 17%, 34%, and 67%, respectively (Venderink et al., 2017).

Box 150.2

PI-RADS v2 Categories

- PI-RADS 1: Very low (clinically significant cancer is highly unlikely to be present)
- PI-RADS 2: Low (clinically significant cancer is unlikely to be present)
- PI-RADS 3: Intermediate (the presence of clinically significant cancer is equivocal)
- PI-RADS 4: High (clinically significant cancer is likely to be present)
- PI-RADS 5: Very high (clinically significant cancer is highly likely to be present)

Based on its superior detection rate for clinically significant cancer, multiparametric MRI might be able to guide and therefore limit the number of biopsies and cores for patients (Amsellem-Ouazana et al., 2005). “In-bore” MRI prostate biopsy is performed with the patient in the MRI unit. It requires highly specialized equipment and is limited by technical considerations such as limited space in the MRI, cost, and time considerations (Beyersdorff and Hamm, 2005). In one recent study of multiparametric MRI prostate biopsy in 223 men compared with TRUS biopsy, 142 (63.7%) had prostate cancer (Pokorny et al., 2014). TRUS prostate biopsy detected 126 cancers (56.5%), including 47 (37.3%) classed as low risk. MRI-directed biopsy detected 99 cases of cancer in 142 men (69.7%) with equivocal or suspicious MRI, of which 6 (6.1%) were low risk. The MRI pathway reduced the need for biopsy by 51%, decreased the diagnosis of low-risk prostate cancer by 89.4%, and increased the detection of intermediate-/high-risk prostate cancer by 17.7%. The estimated negative predictive values (NPVs) of TRUS biopsy and MRI biopsy for intermediate- and high-risk disease were 71.9% and 96.9%, respectively.

Cognitive fusion requires no additional equipment. This approach relies on an experienced operator reviewing a suspicious lesion on MRI and then directing the biopsy needle in the direction of those lesions during the standard TRUS biopsy procedure. A primary disadvantage of this technique is the inability to record and confirm biopsy needle placement and interuser variability (Logan et al., 2014). The utility of this technique will be limited when there are no obvious landmarks in the prostate by which to direct the biopsy.

One of the most promising biopsy techniques is TRUS/MRI fusion via a software platform. It combines the familiarity of real-time TRUS guidance with detailed information from a diagnostic multiparametric MRI and superimposes both images via software image reconstruction. The reconstruction involves image registration or image matching. A prebiopsy MRI must identify target lesions suspicious for cancer based on imaging characteristics. Based on the particular software platform, these targets are delineated before or after MRI data have been loaded onto the software platform. TRUS of the prostate is performed, and MRI and real-time TRUS images are superimposed, creating a three-dimensional prostate reconstruction and allowing rapid identification of the MRI targets for biopsy in a few minutes. Several MRI/US fusion systems are available in the United States and worldwide (Sarkar and Verma, 2018). The most commonly used systems in the United States are the UroNav platform (Phillips/Invivo, Gainesville, FL) and the Artemis platform with ProFuse (Eigen). The UroNav system has been under study at the National Cancer Institute since 2004 and has the largest collection of published data to date. Several other manufacturers are developing systems both in the United States and abroad (Raskolnikov et al., 2014; Sarkar and Verma, 2018).

The different fusion platforms use proprietary systems for image coregistration and fusion. The Artemis system employs a mechanical arm to direct the biopsy. The UroNav system employs a standard handheld probe with localization and tracking data recorded by an external magnetic field generator integrated with existing freehand ultrasound technology. Other differences include varying methods to acquire the transrectal ultrasound image, including freehand sweep through the prostate or mechanical stabilization (Sarkar and Verma, 2018). Real-time image fusion allows the physician to direct the biopsy using standard TRUS spring-loaded needle biopsy technique (Fig. 150.9).

FIG. 150.9 Example of a screen shot when performing transrectal ultrasonography (TRUS) using the UroNav (Invivo) TRUS–magnetic resonance imaging (MRI) fusion biopsy system. *Upper panel* is the real-time ultrasound; *lower panel* shows the MRI. The *red line* outlines the prostate, and the *green circle with the red dot* represents the coregistered lesion of interest. The *yellow line* represents the needle tract. (Courtesy of Dr. Peter Pinto, Urologic Oncology Branch, National Cancer Institute, Bethesda, MD.)

Initial results were reported for two US TRUS/MRI fusion systems: the UroNav and Artemis. A study at the University of California–Los Angeles involving 171 men demonstrated that 94% (16 of 17 patients) with a PIRADS 5 (highly suspicious) MRI lesion had biopsy-positive prostate cancer. A 38% detection rate was found for intermediate- to high-risk prostate cancer identified only on targeted biopsy, with targeted cores three times more likely to detect intermediate- to high-risk disease versus systematic biopsy (Sonn et al., 2013).

An update series of 582 men studied on the UroNav system has demonstrated an increasing correlation between MRI suspicion and Gleason grade for prostate cancer with detection for Gleason 8 or greater prostate cancer showing a 98% sensitivity at the low-moderate cutoff and a 91% NPV at the moderate-high cutoff (Rais-Bahrami et al., 2013). Another TRUS/MRI fusion–guided biopsy study with the UroNav system demonstrated upgrading and detection of prostate cancer with higher Gleason score in 32% of patients compared with traditional 12-core biopsy alone (Siddiqui et al., 2013). Targeted biopsy with the TRUS/MRI fusion technique preferentially detected higher-grade prostate cancer and missed lower-grade tumors.

Implementation of MRI fusion prostate biopsy has expanded greatly over the past 5 years, and there is growing awareness of the importance of mpMRI and fusion biopsy in a variety of clinical settings. These include the initial evaluation of men with elevated PSA; follow-up of men with persistently elevated PSA and previous negative biopsy; active surveillance algorithms for men with low- and very-low-risk prostate cancer; and accurate clinical staging of men diagnosed with prostate cancer (Duvnjak et al., 2018). In a joint consensus statement, the AUA and the Society of Abdominal Radiology (SAR) in 2016 recommended mpMRI with targeted biopsies of PI-RADS lesions with a score greater than or equal to 3 in men with negative previous prostate biopsies and persistently elevated PSA (Rosenkrantz et al., 2016). This strategy was also incorporated in the NCCN Prostate Cancer Early Detection Guidelines in 2018 (NCCN, 2018).

For biopsy-naïve men with elevated PSA, the role of mpMRI and MRI-targeted biopsy is less clear. The PROMIS trial examined this issue, originating in the United Kingdom (Ahmed et al., 2017). In this prospective, paired cohort study of 576 men who completed the study, mpMRI was performed initially but was blinded to both patients and physicians. The patients underwent standard TRUS prostate biopsy (10 to 12 cores) and transperineal mapping prostate biopsies in a saturation fashion (biopsy every 5 mm) to serve as the gold standard reference range for prostate cancer detection in terms of lesion grade and location. The lesions detected on mpMRI were compared with the cancer detected on transperineal mapping to assess the accuracy of MRI in cancer detection. Additionally, the TRUS biopsy performance for cancer detection was also compared with the transperineal mapping reference. **MRI outperformed standard TRUS in prostate cancer detection for clinically significant disease,** with an improved sensitivity (93% vs 48%, respectively) and negative predictive value (89% vs 74%, respectively), while showing decreased specificity (41% vs 96%, respectively) and positive predictive value (51% vs 90%, respectively) (Ahmed et al., 2017).

The PRECISION trial recently reported similar results in the biopsy-naïve population of men with elevated PSA (Kasivisvanathan et al., 2018). In this multicenter trial in Europe and North America, men with elevated PSA referred for prostate biopsy were randomized to MRI-targeted biopsy versus standard 10- to 12-core TRUS biopsy, with the end point of detecting clinically significant cancer. **In this large, well-designed study, MRI-targeted biopsy had a higher detection rate of clinically significant disease and lower detection rate of clinically insignificant disease compared with standard TRUS biopsy** (Kasivisvanathan et al., 2018). These results confirm the previous single-institution study from the National Cancer Institute comparing standard TRUS prostate biopsy with MRI fusion biopsy utilizing the UroNav system, in which MRI fusion biopsies had significantly improved cancer detection for high-risk (clinically significant) tumors (Siddiqui et al., 2015).

Enthusiasm for MRI-targeted biopsies should tempered, however, with the realization that no technique has perfect performance in prostate cancer detection, even when restricted to clinically significant disease. The NCI group examined their large single-institution cohort of MRI biopsies and retrospectively examined the cohort that eventually underwent radical prostatectomy as the gold standard. **In this evaluation, from a center of excellence with a large cohesive multidisciplinary team for prostate MRI and MRI-targeted biopsy, the false-negative rate of mpMRI was 16% for detection of clinically significant cancer.** Of the lesions that were missed, the majority were favorable intermediate risk (Gleason 3 + 4 = 7) in 65%, but the remaining 35% of clinically significant lesions missed had primary Gleason pattern 4 disease (4 + 3 = 7 in 4%, 4 + 4 = 8 in 27%, and 4 + 5 = 9 in 4%) (Borofsky et al., 2018).

Technologies continue to evolve in improving the identification and diagnosis of prostate cancer. Beyond imaging technologies such as ultrasonography and MRI, the use of genomic and other molecular markers will play an increasing role in determining the need for a biopsy and in identifying patients who are in need of a repeat biopsy (Partin et al., 2014). Color Doppler, ultrasound contrast agents, elastography, multiparametric MRI, and TRUS/MRI fusion are undergoing refinements as imaging methods to guide and enhance the accuracy of prostate biopsies (Hong et al., 2014). An intriguing trial comparing mpMRI and multiparametric TRUS, entitled the CADMUS trial (Cancer Detection by Multiparametric Ultrasound of the prostate) has been initiated in the United Kingdom, which should provide prospective data comparing differing prostate biopsy strategies for the first time (Grey et al., 2018). Until these techniques are proved superior in the localization and diagnosis of prostate cancer, systematic

TRUS gray-scale 12-core needle biopsy will continue to be regarded as the gold standard for the diagnosis of prostate cancer.

Key Points: Prostate Biopsy

- TRUS and/or MRI alone cannot diagnose prostate cancer without a tissue biopsy.
- Local prostate anesthesia is commonplace and most useful when using extended-core biopsy schemes.
- Patients undergoing TRUS-guided prostate biopsy require oral antibiotic prophylaxis for up to 24 hours perioperatively.
- Sextant biopsy of the prostate for prostate cancer detection is inadequate, and systematic biopsy procedures should include a minimum of 12 cores based on AUA recommendations.
- Advanced ultrasound techniques (color and power Doppler, contrast-enhanced TRUS, elastography) can improve cancer detection but do not reliably identify all malignant foci and thus cannot obviate the need for systematic biopsy at the present time.
- TRUS/MRI fusion is a promising technique that takes advantage of the strengths of each modality when performing prostate biopsy.

Pathology of Prostatic Neoplasia

Jonathan I. Epstein MD

This chapter covers the pathology of adenocarcinoma of the prostate from its precursor lesions to invasive carcinomas, from needle biopsies to radical prostatectomies. Other tumors involving the prostate are also discussed. In particular, practical points of pathology are emphasized, which are critical for urologists to know for the management of their patients.

Prostatic Intraepithelial Neoplasia

Prostatic intraepithelial neoplasia (PIN) consists of architecturally benign prostatic acini or ducts lined by cytologically atypical cells, and PIN is subclassified into low-grade PIN (LGPIN) and high-grade PIN (HGPIN) (McNeal, 1989; McNeal and Bostwick, 1986) (Fig. 151.1). **Diagnostic reports should not comment on LGPIN.** First, pathologists cannot reproducibly distinguish between LGPIN and benign prostate tissue (Epstein et al., 1995). Second, when LGPIN is diagnosed on needle biopsy, these patients are at no greater risk for having carcinoma on repeated biopsy than are men with a benign biopsy finding (Epstein and Herawi, 2006). Evidence that HGPIN is a precursor to some prostate carcinomas includes the following: There is an increase in the size and number of HGPIN foci in prostates with cancer compared with prostates without carcinoma; with increasing amounts of HGPIN, there is a greater number of multifocal carcinomas; and biomarkers and molecular changes show similarity between HGPIN and carcinoma (Bostwick et al., 1996; Häggman et al., 1997). About 20% of HGPIN lesions harbor a *TMPRSS2:ERG* fusion gene, which is a common molecular abnormality detectable in about 50% of prostate cancers (Cerveira et al., 2006; Perner et al., 2007). The finding of zones of HGPIN from which there appears to be budding off glands of carcinoma is further histologic evidence that HGPIN is a precursor to some prostate carcinomas (McNeal et al., 1991).

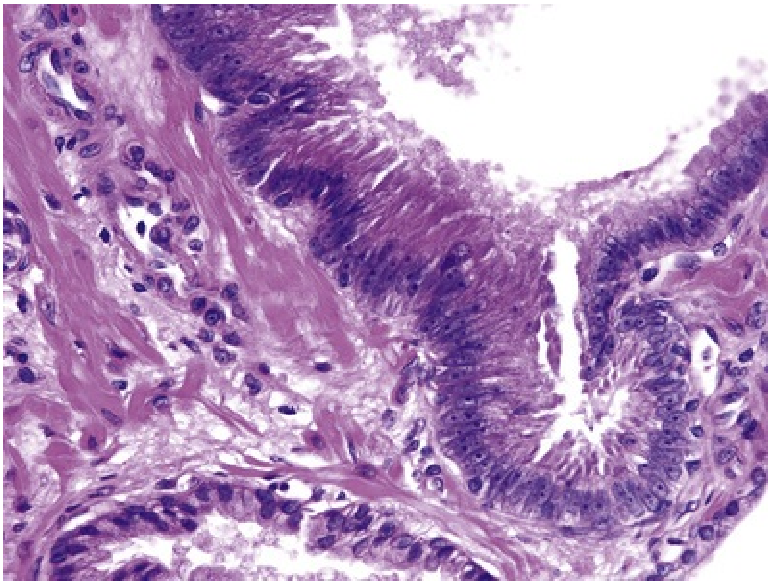

FIG. 151.1 High-grade prostatic intraepithelial neoplasia. Note cytologically atypical cells with prominent nucleoli in an architecturally benign gland *(top),* contrasted to a benign gland *(bottom).*

The incidence of HGPIN on biopsy averages in the 4% to 5% range (Epstein and Herawi, 2006). There is a tremendous variation in the percentages reported, ranging from 0% to 25%. The most likely explanation accounting for this variation is interobserver threshold. The distinction between LGPIN and HGPIN is based on the prominence of the nucleoli. This is a subjective exercise, and those pathologists with a lower threshold regarding the definition of prominent nucleoli will have a higher incidence of HGPIN. **The mean risk for cancer is 20% to 30% on subsequent biopsy within 1 year after diagnosis of HGPIN, which is not significantly higher than the risk for carcinoma following a repeat biopsy after a benign diagnosis** (Epstein and Herawi, 2006)**. In the majority of studies, serum prostate-specific antigen (PSA) levels, results of digital rectal examination, and transrectal ultrasonography findings do not enhance the prediction of who is more likely to exhibit carcinoma on repeat biopsy.** PIN by itself does not give rise to elevated serum PSA values (Epstein and Herawi, 2006; Ronnett et al., 1993). Approximately 80% of the cancers detected on repeat biopsy are Gleason score 6 (Grade Group 1) (Tosoian et al., 2018). **For patients diagnosed with unifocal HGPIN on extended initial core sampling, a repeat biopsy within the first year is unnecessary in the absence of other clinical indicators of cancer. HGPIN on greater than or equal to 2 cores is associated with approximately the same rick of subsequent cancer as an “atypical suspicious for carcinoma”**

diagnosis, where follow up is warranted with serum or urine tests, imaging, and in some cases repeat biopsy with relative increased sampling of the atypical site (Abdel-Khalek et al., 2004; Epstein and Herawi, 2006; Merrimen et al., 2009, 2010).

There are numerous benign and malignant mimickers of HGPIN. It may be difficult to distinguish between outpouchings or tangential sections of HGPIN with adjacent small atypical glands (PINATYP) as opposed to PIN with associated infiltrating carcinoma (Kronz et al., 2001). Most of these cases will require immunohistochemistry for basal cell markers, where cancer should be diagnosed only when there is a large cluster of entirely negative glands. The risk for carcinoma after a diagnosis of PINATYP is the same as an “atypical suspicious for carcinoma” diagnosis.

The significance of HGPIN on transurethral resection (TUR) is not clear, with conflicting data as to the risk for subsequent discovery of cancer (Gaudin et al., 1997; Pacelli and Bostwick, 1997). In an elderly patient with HGPIN on TUR, often no further workup is instituted. In a younger man, a more aggressive workup to rule out a clinically significant tumor may be warranted. **HGPIN is a precursor lesion to many peripheral intermediate- to high-grade adenocarcinomas of the prostate.** However, PIN need not be present for carcinoma to arise. Low-grade carcinomas, especially those present within the transition zone, are not closely related to HGPIN.

Intraductal carcinoma of the prostate (IDC-P) has either architectural or cytologic atypia that clearly exceeds that seen in HGPIN (Cohen et al., 2007; McNeal and Bostwick, 1986; McNeal and Yemoto, 1996a; McNeal et al., 1986; Robinson et al., 2012; Rubin et al., 1998; Wilcox et al., 1998). Rarely, IDC-P may be identified on biopsy material in the absence of infiltrating carcinoma (Guo and Epstein, 2006). IDC-P on prostate biopsies is frequently associated with high-grade cancer and poor prognostic parameters at radical prostatectomy (Guo and Epstein, 2006). These findings support the idea that in most cases IDC-P represents intraductal spread of carcinoma within preexisting ducts and acini and that IDC-P in the vast majority of cases should not be categorized as a preinvasive neoplastic condition (Haffner et al., 2016; Miyai et al., 2014). In the rare case in which IDC-P is treated by radical prostatectomy and no invasive cancer is found, the surgery is justified, as in these cases IDC-P is a high-grade preinvasive lesion that includes a high risk for developing invasive high-grade cancer. **We recommend that patients with IDC-P only on biopsy be treated with definitive therapy, although some clinicians perform repeat biopsy to**

document invasive carcinoma before initiating therapy. In cases that are borderline between IDC-P and HGPIN, repeat biopsy is warranted. Rarely, IDC-P will be seen on biopsy with only a Gleason score 3+3=6. It is important not to consider the patient to have only low-grade carcinoma and a candidate for active surveillance, because there is a high risk that there is unsampled higher-grade cancer present (Khani and Epstein, 2015).

Adenocarcinoma

Staging Classification

Stages T1a (≤5% cancer) and T1b (>5%) adenocarcinomas of the prostate are clinically unsuspected tumors that are discovered in either TUR of the prostate (TURP) or enucleation specimens removed for benign prostatic hyperplasia (Epstein et al., 2007). Stage T1c disease refers to nonpalpable prostate cancer found on needle biopsy, usually performed for an abnormal serum PSA level. If a patient undergoes radical prostatectomy, stages T1a to T1c are converted to pT2 or pT3 if the tumor is organ confined or shows extraprostatic extension (EPE), respectively. Pathologic stage T2 is defined as tumor localized to the prostate, which was until recently further subcategorized into T2a to T2c depending on the extent of cancer in an analogous manner to clinical staging of T2 disease. However, numerous studies have shown that subdividing pathologic stage T2 disease has no prognostic significance. The reason for this finding is that bilateral prostate cancer may represent (1) a dominant tumor nodule with contralateral small, low-grade, clinically insignificant tumor; (2) significant discrete right and left tumor nodules; or (3) a single, large, confluent tumor mass involving both sides. Consequently, the designation “pathologic stage T2c” (bilateral cancer) has no meaning, and the 2018 TNM (tumor, node, metastases) classification has as a mandatory field noting only pT2 with further subclassification into “T2a” or “T2b” or “T2c” as optional (Kheirandish and Chinegwundoh, 2011; van der Kwast et al., 2011). “Stage T2+” (stage T2x) refers to a tumor with no identifiable tumor in extraprostatic tissue but with a positive margin because of the surgeon's cutting into the prostate (intraprostatic incision). Because the edge of the prostate has been left in the patient, the pathologic stage cannot be assessed in the area of the intraprostatic incision. Pathologic stage T3 represents a tumor that has extended out of the prostate gland, which is further subclassified into T3a and T3b, depending on whether the extraprostatic tumor is without or with seminal vesicle invasion, respectively. Microscopic bladder neck invasion is pT3a.

Location

In clinical stage T2 carcinomas and in 85% of nonpalpable tumors

diagnosed on needle biopsy (stage T1c), the major tumor mass is located in the posterior portion of the prostate in the peripheral zone (Byar and Mostofi, 1972; Epstein et al., 1994a; McNeal, 1969). Approximately 15% of radical prostatectomy specimens show predominantly anterior tumors, some in the transition zone and others in the anterior horn of the peripheral zone (Al-Ahmadie et al., 2008). Anterior prostates tend to have a better prognosis and less seminal vesicle involvement than tumors located posteriorly (Kim et al., 2016). Adenocarcinoma of the prostate is multifocal in more than 85% of cases (Byar and Mostofi, 1972). In many of these bilateral or multifocal tumor cases, the other tumors are small, low grade, and clinically insignificant. In cases with bilateral cancer at radical prostatectomy, the contralateral tumor to the positive biopsy side at radical prostatectomy is typically small. However, 20% have some contralateral adverse pathology in terms of size, EPE, grade, or margins (Yoon et al., 2008).

Spread of Tumor

Because the prostate lacks a discrete histologic capsule, *extraprostatic extension,* rather than *capsular penetration,* is the preferable term to describe a tumor that has extended out of the prostate into the periprostatic soft tissue (Ayala et al., 1989). Some authors use the term *capsular invasion* when they believe that the “capsule” is infiltrated by a tumor but the tumor does not extend out of the prostate. Because there is no such entity as the prostatic capsule, “capsular invasion” makes no sense. Peripherally located adenocarcinomas of the prostate tend to extend out of the prostate through perineural space invasion (Villers et al., 1989). EPE preferentially occurs posteriorly and posterolaterally, paralleling the location of most adenocarcinomas.

Further local spread of the tumor may lead to seminal vesicle invasion, which is diagnosed when a tumor extends into the muscle wall of the seminal vesicle. The most common route of seminal vesicle invasion is by tumor penetration out of the prostate at the base of the gland, with growth and extension into the periseminal vesicle soft tissue and eventually into the seminal vesicles. Less commonly, there may be direct extension through the ejaculatory ducts into the seminal vesicles or direct extension from the base of the prostate into the wall of the seminal vesicles. Almost never are there discontinuous metastases to the seminal vesicle (Ohori et al., 1993). Local spread of prostate cancer may also rarely involve the rectum, where it may be difficult to distinguish from a rectal primary tumor (Fry et al., 1979; Lane et al., 2008).

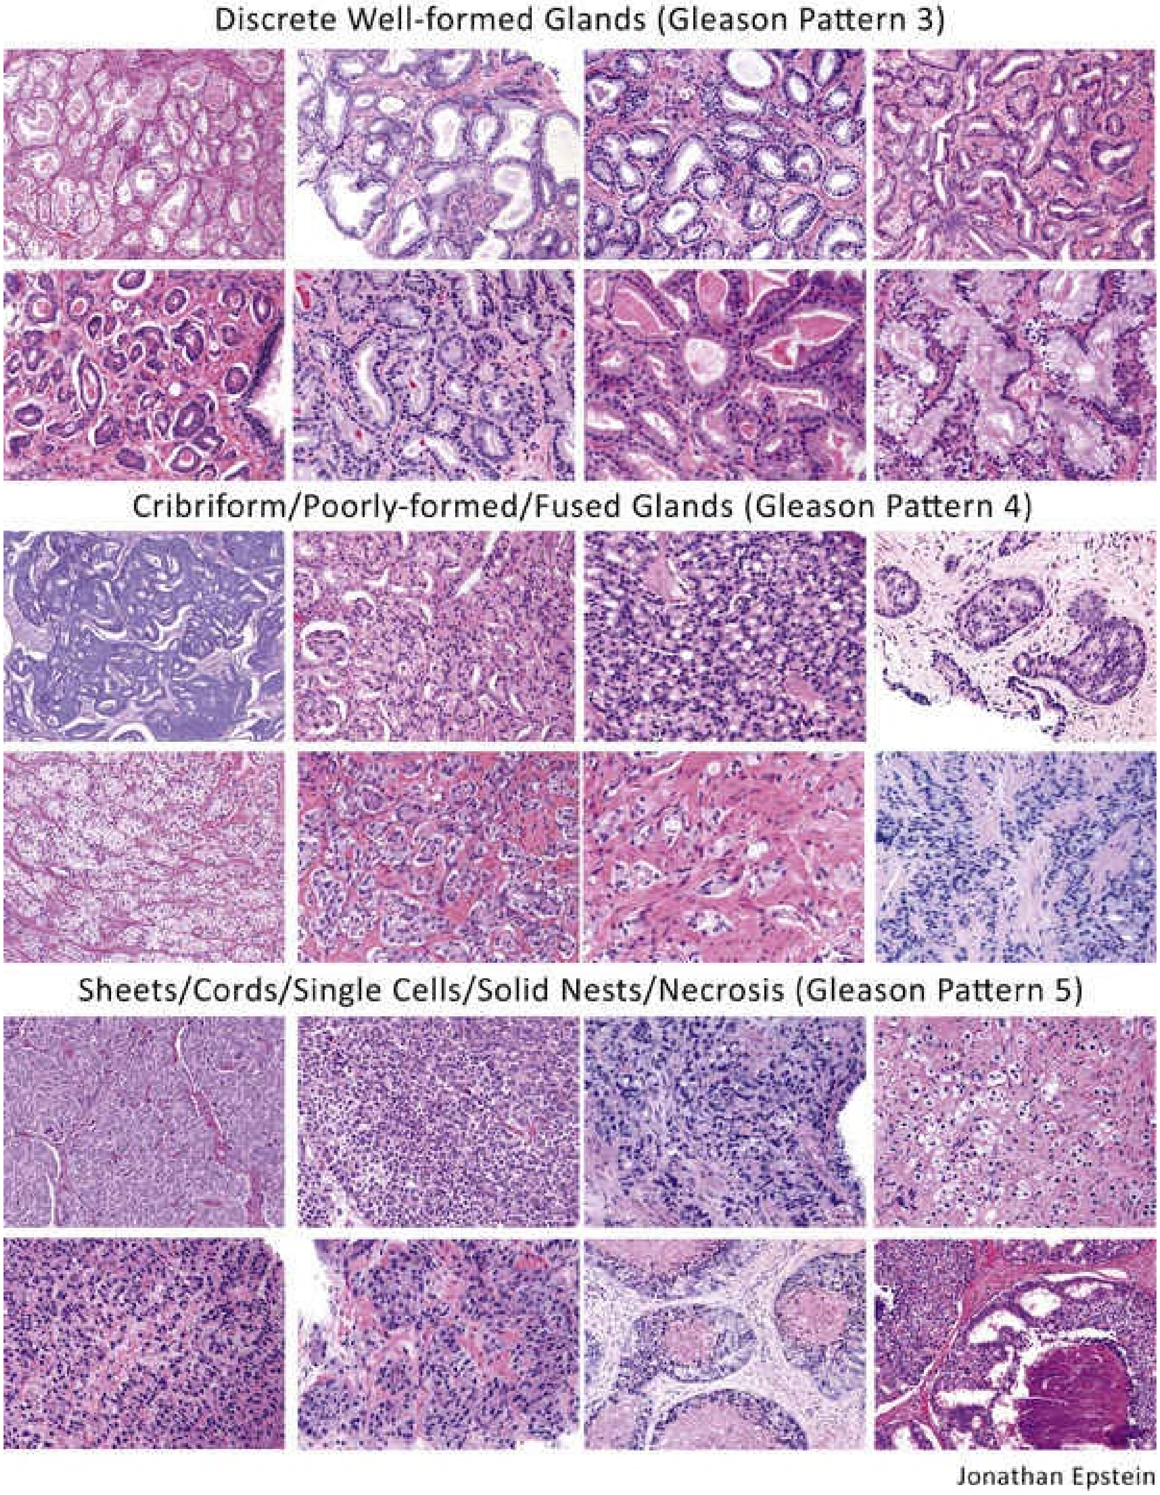
The most frequent sites of metastatic prostate carcinoma are lymph nodes and bones. Prostate cancer may present with metastases to the left supradiaphragmatic, typically the supraclavicular, lymph nodes (Cho and Epstein, 1987). Lung metastases from prostate carcinoma are extremely common at autopsy, and almost all cases involve bone as well (Varkarakis et al., 1974). Metastatic lesions usually take the form of multiple small nodules or diffuse lymphatic spread rather than large metastatic deposits. Clinically, prostate carcinoma metastatic to the lung is usually asymptomatic. In addition to lymph nodes, bones, and lung, the next most common regions for the spread of prostate cancer at autopsy are bladder, liver, and adrenal gland (Hess et al., 2006).

Tumor Volume

In general, the size of a prostate cancer correlates with its stage. EPE is uncommon in tumors less than 0.5 cm^3, and tumors less than 4 cm^3 uncommonly show lymph node metastases or seminal vesicle invasion (McNeal et al., 1990). Tumor volume is also proportional to grade (see the following discussion). The location and grade of the tumor also modulate the effect of tumor volume (Christensen et al., 1990; Greene et al., 1991; McNeal et al., 1990). For example, **transition zone tumors extend out of the prostate at larger volumes than do peripheral zone tumors because of their lower grade and greater distance from the edge of the gland.** Reporting of tumor volume in various specimens is discussed later in this chapter.

Grade

The Gleason system is based on the glandular pattern of the tumor as identified at relatively low magnification (Gleason and Mellinger, 1974; Mellinger et al., 1967) (Fig. 151.2). Cytologic features play no role in the grade of the tumor. **Architectural patterns are identified and assigned a grade from 1 to 5, with 1 being the most differentiated and 5 being undifferentiated**. **Although in the original Gleason system, the most common and second most common grades were combined, in 2005 the Gleason system was updated and modified with one change being that on biopsy the *most common* and *highest-grade* patterns on a given core were added to result in the Gleason score** (Epstein et al., 2005). If a tumor has only one histologic pattern, then for uniformity, both patterns are assigned the same grade. In theory, however, the Gleason scores range from 2 (1 + 1 = 2), which represents tumors uniformly composed of Gleason pattern 1 tumor, to 10 (5 + 5 = 10), which represents totally undifferentiated tumors. Most cases with divergent patterns, especially on needle biopsy, do not differ by more than one pattern. It is reasonable to assign a full Gleason score even to small foci of cancer on needle biopsy because it has been demonstrated that the grade assigned to these minimal cancers is just as accurate compared with cases with more extensive cancer on biopsy (Steinberg et al., 1997).



Discrete Well-formed Glands (Gleason Pattern 3)
Cribriform/Poorly-formed/Fused Glands (Gleason Pattern 4)
Sheets/Cords/Single Cells/Solid Nests/Necrosis (Gleason Pattern 5)

Jonathan Epstein

FIG. 151.2 The Gleason grading system and correlates with Grade Group morphologies. *From left to right: First row:* Closely packed uniformly sized and shaped large glands; large variably sized and shaped glands, some with infolding; uniform medium-sized glands; variably sized glands. *Second row:* Occasional tangentially sectioned glands among well-formed small glands; occasional tangentially sectioned glands among well-formed glands

with open lumina; back-to-back discrete glands; branching glands. *Third row:* Large irregular cribriform glands with well-formed lumina; irregular cribriform glands with slitlike lumina, glomeruloid structures, and fused glands; irregular cribriform glands with small round lumina; small round cribriform glands. *Fourth row:* Poorly formed glands with peripherally arranged nuclei; small poorly formed glands; small poorly formed glands; fused poorly-formed glands. *Fifth row:* Sheets of cancer; sheets of cancer with rosette formation; small nests and cords of tumor with scattered clear vacuoles; individual cells. *Sixth row:* Nests and cords of cells with only a vague attempt at lumina formation; solid nests of cancer; solid nests with comedonecrosis; cribriform glands with central necrosis.

It is not recommended that Gleason score 2 to 4 be assigned for adenocarcinoma of the prostate on needle biopsy because (1) most tumors graded as Gleason score 2 to 4 on needle biopsy are graded higher when reviewed by uropathology experts (Steinberg et al., 1997); (2) there is poor reproducibility in the diagnosis of Gleason score 2 to 4 on needle biopsy even among uropathology experts (Allsbrook et al., 2001); and (3) most important, assigning a Gleason score of 2 to 4 to an adenocarcinoma on needle biopsy is not necessarily associated with such favorable findings at radical prostatectomy (Epstein, 2000). Whereas 24% of pathologists rendered a diagnosis of Gleason score 2 to 4 on biopsy in 1991, this decreased to 2.4% in 2001 and is even much less common in today's practice (Ghani et al., 2005). **Gleason patterns 1 and 2 are for the most part not diagnosed on needle biopsy specimens, such that a problem with the current system is that Gleason score 6 is typically the lowest grade assigned on biopsy material. However, the Gleason scale ranges from 2 to 10, so patients are consequently unduly concerned when told they have Gleason score 6 cancer on biopsy; they logically but incorrectly assume that their tumor is in the midrange of aggressiveness.** Another consequence of the updated Gleason grading system is that there is an expanded definition of Gleason pattern 4 to include a broader range of histologic patterns and a greater proportion of cases. **There are several prognostic consequences of the reclassification of many former Gleason score 6 tumors to Gleason score 7 in the modified system. Gleason score 6 tumors are currently more homogeneous and have a uniformly more favorable prognosis.** For example, virtually no organ-confined Gleason score 6 tumor is associated with progression after radical prostatectomy, whereas this occasionally occurred using the original Gleason system (Hernandez et al., 2008). **In addition, Gleason score 6 carcinomas using the updated Gleason system do not have the ability to metastasize to lymph nodes** (Nunez

Bragayrac et al., 2017; Ross et al., 2012). Extraprostatic extension is also uncommon with Gleason score 3+3=6 at radical prostatectomy, reportedly seen in 0.28% of Gleason score 6 tumors in one study, with a higher frequency in our own experience with 3.9% for focal extraprostatic extension and 2.4% for nonfocal extraprostatic extension. Multiple cores of Gleason score 6 still correlate with favorable findings at radical prostatectomy (Ellis et al., 2013). **Using the modified Gleason system, in a study from Johns Hopkins Hospital of 6462 men, almost 95% and 97% of patients with Gleason score 6 cancer at biopsy and radical prostatectomy (no tertiary pattern 4 at radical prostatectomy), respectively, were predicted to be cured of disease at 5 years after radical prostatectomy** (Pierorazio et al., 2013b)**. Using the modified Gleason system, this study showed that Gleason score 3 + 4 = 7 tumor has a very favorable prognosis, with an estimated 5-year biochemical-free survival of 83% and 88% for biopsy and radical prostatectomy, respectively. Gleason scores 9 to 10 tumor had almost twice the risk for progression compared with Gleason score 8. Oversimplification of the Gleason grade classification, such as combining Gleason scores 8 to 10 or classifying patients into low-, intermediate-, and high-risk categories based on Gleason scores less than 7, 7, and greater than 7, loses critical prognostic information. A more contemporary grouping of Gleason scores based on differing prognoses is as follows: Gleason scores less than or equal to 6; 3 + 4 = 7; 4 + 3 = 7; 8; 9 to 10, which reflect Grade Groups 1 to 5, respectively (Box 151.1)** (Pierorazio et al., 2013b). The new Grade Groups system was validated in a multi-institutional study of almost 21,000 radical prostatectomy and 16,000 needle biopsy specimens assessing biochemical recurrence (BCR) (Epstein et al., 2016b). Subsequently, numerous studies have validated Grade Groups in relation to BCR after radiation, risk for distant metastases, and prostate cancer–specific mortality (Berney et al., 2016; Leapman et al., 2017). The new Grade Group system has been recommended by the 2016 World Health Organization (WHO), the College of American Pathology (CAP), and the 8th Edition AJCC Cancer Staging Manual. As of January 2018, Grade Groups need to be reported alongside Gleason grades for laboratories to be accredited by CAP, which is the major accrediting agency for pathology laboratories in the United States.

Box 151.1

Grade Groups Definitions

- Grade Group 1 (Gleason score 3 + 3 = 6): Only individual discrete well-formed glands
- Grade Group 2 (Gleason score 3 + 4 = 7): Predominantly well-formed glands with lesser component of poorly formed/fused/cribriform glands
- Grade Group 3 (Gleason score 4 + 3 = 7): Predominantly poorly formed/fused/cribriform glands with lesser component of well-formed glands
- Grade Group 4 (Gleason score 8)
  - Poorly formed/fused/cribriform glands or
  - Predominantly well-formed glands and any lesser component lacking glands
  - Predominantly lacking glands and second most common component of well-formed glands
- Grade Group 5 (Gleason scores 9 to 10): Lack gland formation (or with necrosis) with or without poorly formed/fused/cribriform glands

The Gleason grade on biopsy material has also been shown to correlate fairly well with that of the subsequent prostatectomy specimen (Fine and Epstein, 2008). In general, a Gleason score less than or equal to 6 on biopsy corresponds to a Gleason score less than or equal to 6 in the radical prostatectomy in about 65% of cases. An unavoidable cause of discrepant grading between the biopsy and subsequent prostatectomy specimen is that caused by sampling error by the needle biopsy. The following factors are associated with upgrading from the needle biopsy to the radical prostatectomy: increased cancer extent on biopsy; increased serum PSA levels; smaller prostates; and fewer cores sampling the prostate (Epstein et al., 2012).

Some men with low-grade cancers develop high-grade tumors after several years. It is not clear whether the residual low-grade cancer progressed or whether there was a subsequent development of a multifocal, more aggressive tumor. Although, in general, larger tumors are high grade and small tumors are low grade, exceptions occur (Epstein et al., 1994b). There is a tendency to hypothesize that tumors begin as low-grade tumors and, on reaching a certain size, dedifferentiate into higher-grade lesions, accounting for the relationship between size and grade. Alternatively, high-grade tumors may be high grade at their inception but are detected at an advanced size because of their rapid growth. Similarly, low-grade tumors may evolve so slowly that they tend to be detected at lower volumes. From a practical standpoint, during a 2- to 3-year period after biopsy, more than 80% of men's prostate cancer grades remain stable (Sheridan et al., 2008).

Assessment of Needle Biopsy Specimens

Processing

When biopsy specimens are taken from different sextant areas of the prostate, they should be submitted to pathology in separate containers (Box 151.2). As long as cores are submitted in separate containers, or the cores are in the same container yet specified by the urologist as to their location (i.e., by different colored inks), pathologists should assign individual Gleason scores to separate cores (Epstein et al., 2005, 2016a, 2017). If cores are combined in a container without designation, most pathologists provide an overall Gleason score as if all the cores were one long core.

Box 151.2

Reasons to Submit Needle Cores in Separate Jars for Each Sextant Site

- In “atypical” cases, the atypical site can be preferentially targeted on repeated biopsy, in addition to other sites.
- More specific location of cancer helps pathologists target additional tissue or block sampling in cases with no cancer on initial sampling of radical prostatectomy.
- Knowledge of sextant site helps pathologists to recognize certain diagnostic pitfalls (i.e., seminal vesicle tissue or central zone mimicking high-grade prostatic intraepithelial neoplasia at the base and Cowper gland mimicking cancer at the apex).
- With brachytherapy, this helps target areas where extra seeds can be distributed.
- Having a maximum of two cores per block or slide preparation with

complete visualization of cores helps prevent missing small foci of cancer that could be “buried” in the paraffin block.

- Maximum of two cores per block or slide helps prevent core fragmentation where one cannot determine the number of involved cores, their percentage involvement, and the highest grade of cancer in the case.

Differential Diagnosis

The underdiagnosis of limited adenocarcinoma of the prostate on needle biopsy is one of the most frequent problems in prostate pathology (Epstein, 2004). There are also numerous benign mimickers of adenocarcinoma of the prostate (Srigley, 2004). In some of these cases, the use of antibodies to high-molecular-weight cytokeratin and p63 may resolve the diagnosis (Wojno and Epstein, 1995). Benign glands contain basal cells and are labeled with these antibodies, whereas prostate cancer shows no staining. Immunohistochemistry with antibodies to α-methylacyl-CoA racemase, which preferentially labels prostatic carcinoma and HGPIN, can also be used as an adjunct in the diagnosis of limited cancer, yet pathologists must be careful because false-positive and false-negative staining with α-methylacyl-CoA racemase have been reported (Jiang et al., 2004, 2005). Nuclear immunoreactivity for ERG can be used as a surrogate for *TMPRSS2:ERG* gene fusion, a specific molecular event seen in approximately 50% of prostate carcinomas. The major limitation of this technique that limits its utility is that on limited foci of carcinoma on needle biopsy, the sensitivity may be somewhat lower, to around 30% to 40%, and positivity does not exclude HGPIN (Shah et al., 2013; Tomlins et al., 2012).

In certain cases, there are findings suggestive of, but not diagnostic of, carcinoma. **The incidence of atypical needle biopsy specimens is about 5%** (Epstein and Herawi, 2006)**. The likelihood of cancer after an atypical diagnosis is about 40%** (Burks et al., 2017; Chan and Epstein, 1999; Epstein and Herawi, 2006; Iczkowski et al., 1997; Tosoian et al., 2018)**. Clinical parameters, such as serum PSA levels, do not help in stratifying which men with atypical glands are at increased risk for being diagnosed with cancer. Approximately 80% of the subsequently detected cancers are Gleason score 6 (Grade Group 1), with the remaining cases of higher grade, including 5% with Gleason scores 8 to 10 (Grade Groups 4 to 5). Consequently, for cases with atypical glands on biopsy, follow–up is warranted with serum or urine tests, imaging, or repeat biopsy with relatively increased sampling of the atypical gland sites. Only about 40% of men have a repeat biopsy after a**

diagnosis of atypical glands suspicious for carcinoma (Burks et al., 2017)**. Cases diagnosed as atypical have the highest likelihood of being changed on expert review, and urologists should consider sending such cases for consultation to attempt to resolve the diagnosis as either definitively benign or malignant before subjecting the patient to repeat biopsy** (Chan and Epstein, 2005).

Prognosis

Adverse findings on needle biopsy, in terms of Gleason grade and tumor extent, generally predict adverse findings accurately in the radical prostatectomy specimen. However, as a result of sampling error, favorable findings on needle biopsy do not necessarily predict favorable findings in the radical prostatectomy specimen. The ways in which cancer may be measured on needle biopsy include number of positive cores, total millimeters of cancer among all cores, percentage of cancer per core, and total percentage of cancer in the entire specimen. An equal number of studies claim superiority of one technique over the other, with no one technique adopted uniformly (Epstein, 2011). It is proposed that pathologists report the number of positive cores along with one other measurement of tumor extent. By combining needle biopsy grade with clinical stage and serum PSA values, the extent of cancer within the prostate can be more accurately predicted (Makarov et al., 2007).

Although there are some conflicting data, the cumulative analysis shows a higher incidence of EPE in men with perineural invasion on prostate needle biopsy (Cozzi et al., 2013; Truong et al., 2017). Perineural invasion on biopsy is prognostic in men undergoing external-beam radiotherapy, but is less so with brachytherapy (Harnden et al., 2007). Perineural invasion should be noted on the biopsy pathology report. There are data showing that atrophy and associated inflammation are linked with prostate carcinogenesis (DeMarzo et al., 2003; Platz et al., 2017). However, atrophy of all morphologic types is very common on needle biopsy and is not associated with an increased risk for cancer or PIN on subsequent biopsy (Postma et al., 2005).

Probably the most powerful predictor of prognosis on biopsy is the Gleason score, which can be used to predict multiple outcomes including (1) pathologic stage; (2) side-specific EPE; (3) EPE into the neurovascular bundle; (4) progression after radical prostatectomy; (5) candidates for brachytherapy; (6) prognosis after radiotherapy; (7) candidates for active surveillance; (8) intervention criteria after active surveillance; (9) prognosis

after cryotherapy; (10) prognosis after high-intensity focused ultrasonography (HIFU); and (11) candidates for focal therapy (Epstein, 2013). Within Gleason score 7 on biopsy, increasing percentage of Gleason grade 4 correlates with adverse pathology at radical prostatectomy and biochemical recurrence (Cole et al., 2016). Men with needle biopsies showing Gleason score 3+4=7 with limited percent pattern 4 may also be candidates for active surveillance, factoring in patient's age, comorbidity, imaging results, extent of cancer on biopsy, and patient preferences. Consequently, it is recommended that pathologists report percent pattern 4 for Gleason score 3+4=7 at biopsy, and it is optional for Gleason score 4+3=7.

Assessment of Transurethral Resection Specimens

Processing

The recommended system is based on the percentage of the specimen involved by tumor, with 5% being the cutoff between stages T1a and T1b (Cantrell et al., 1981). All stage T1b tumors are detected by the processing of between 6 and 8 cassettes of a TUR specimen. By processing 8 to 10 cassettes, more than 90% of stage T1a lesions are identified (Murphy et al., 1986; Newman et al., 1982; Rohr, 1987; Vollmer, 1986). Depending on the institution, all TUR tissues may be examined in men younger than 65 years of age in whom aggressive therapy for stage T1a disease might be pursued.

Differential Diagnosis

One of the most common lesions to be confused with low-grade adenocarcinoma is adenosis (atypical adenomatous hyperplasia) (Gaudin and Epstein, 1994, 1995). Approximately 1.6% of benign TUR specimens and 0.8% of all needle biopsy specimens contain adenosis. It is characteristically found in the transition zone of the prostate, is frequently multifocal, and most often is an incidental finding in TURs performed for urinary obstruction. **Although adenosis mimics carcinoma, there is no evidence suggesting that patients with adenosis have an increased risk for harboring or developing adenocarcinoma of the prostate.**

Assessment of Radical Prostatectomy

Specimens

Assessment

Within institutions that do not totally embed radical prostatectomy specimens, there are sampling techniques that provide accurate pathologic staging (Hall et al., 1992; Sehdev et al., 2001). **Whole-mount sectioning of the prostate provides more aesthetically pleasing sections for teaching and publication, yet the information obtained by routine sections is identical.**

Prognosis

Gleason Score.

It is recommended that pathologists assign a separate grade to each major tumor nodule (Epstein et al., 2017). Most often, the largest tumor is associated with the highest stage and highest grade and is referred to as the "dominant nodule." If there are several nodules where the smaller nodule is either of higher stage or grade, one can descriptively refer to them as nodule #1, nodule #2, and so on, and record the grade for each nodule separately. **The Gleason score at radical prostatectomy correlates well with prognosis. The 5-year postoperative biochemical risk, free of disease, is 96.6%, 88.1%, 69.7%, 63.7%, and 34.5% for Gleason scores less than or equal to 6 (Grade Group 1); 3 + 4 = 7 (Grade Group 2); 4 + 3 = 7 (Grade Group 3); 8 (Grade Group 4); and 9 to 10 (Grade Group 5), respectively** (Pierorazio et al., 2013b). **A tertiary (third) grade pattern is recorded typically when there is a nodule with Gleason score 3 + 4 = 7 or 4 + 3 = 7 and a minor (<5%) component of Gleason pattern 5** (Epstein et al., 2017). The presence of a tertiary higher-grade component is associated with an increased risk for biochemical recurrence. In some studies, the presence of a tertiary pattern raises the risk for recurrence to a level intermediate between those of cancers without a tertiary component in the same Gleason score category and cancers in the next higher Gleason score category, and in some studies elevates the risk to the next highest Gleason score (Borhan and Epstein, 2017; Jang et al., 2017; Pan et al., 2000; Trock et al., 2009). In support of keeping 3 + 4 = 7 (Grade Group 2) with tertiary 5 and 4 + 3 = 7 (Grade Group 3) with tertiary 5 within their respective Grade Groups with a notation of tertiary 5, is that the less than 5% higher grade component does not increase the risk for lymph node metastases within a given Grade Group (Diolombi and Epstein, 2017). Within Gleason score 7 at radical prostatectomy, the percent of Gleason pattern 4 adds significantly to predicting postoperative prognosis, and it is recommended that pathologists report this added detailed information (Sauter et al., 2016).

Lymph Node Metastases.

The incidence of lymph node metastases has declined markedly in recent years because earlier tumors are detected by screening techniques. The incidence of nodal metastases is related to the clinical stage, preoperative PSA level, and biopsy grade, with some surgeons not removing pelvic lymph nodes in men with a low risk for metastases. Regional lymph node metastases at radical prostatectomy are uncommon with Gleason scores less than 8. The incidence for Gleason scores 3 + 3 = 6, 3 + 4 = 7, and 4 + 3 = 7 are 0%, 0.6%, and 4.3%, respectively (Diolombi and Epstein, 2017). Almost all patients with positive lymph nodes who undergo radical prostatectomy eventually show progression of their disease, indicative of distant occult metastases. The 15-year biochemical–recurrence-free, metastases-free, and cancer-specific survival for men undergoing radical prostatectomy with positive nodes is 7.1%, 41.5%, and 57.5%, respectively. Predictors of biochemical recurrence, metastases, and death from prostate cancer in multivariate analysis include prostatectomy Gleason score and the number and percent of positive lymph nodes, respectively (Pierorazio et al., 2013a).

Extraprostatic Extension and Seminal Vesicle Invasion.

The prostatic capsule is not well defined histologically, especially at the apex, the base, and anteriorly (Ayala et al., 1989). **Because the prostate lacks a discrete capsule, the term *extraprostatic extension*, rather than *capsular invasion* or *capsular penetration*, is recommended to denote non–organ-confined disease.** It can be difficult to recognize EPE because the boundaries where the prostate ends can be vague, and the tumor can also induce a dense desmoplastic response in the periprostatic adipose tissue (Epstein, 2001). The degree of EPE varies from only a few glands outside the prostate, which we term *focal extraprostatic extension*, to cases with more extensive extraprostatic spread, which we designate *nonfocal extraprostatic extension*. **The degree of EPE correlates with the risk for progression after radical prostatectomy** (Epstein, 2001; Maubon et al., 2016). Other more objective measurements of quantifying the extent of EPE have been proposed, but they correlate well with the subjective "focal" versus "nonfocal" dichotomy, and none have proven sufficiently superior to recommend as the preferred method (Magi-Galluzzi et al., 2011; van Veggel et al., 2011). **Seminal vesicle invasion is a much more dire prognostic finding, with a 65% 5-year progression rate after surgery** (Epstein, 2001; Pierorazio et al., 2011).

Margins.

Novara et al. (2012) reported the mean rate of positive margins in the robotic-assisted radical prostatectomy series, published between 2008 and 2011 (each including >100 cases), to be 15%, which ranged from 6.5% to 32%. **Only approximately 50% of men with positive margins progress after radical prostatectomy** (Epstein et al., 1993). A major source of this discrepancy is that even in cases in which margins histologically appear to be positive, additional tissue removed from the site does not always show a tumor (Epstein, 1990). A few studies have documented the performance of frozen section along the length of the prostate in the region of the neurovascular bundle with a positive intraoperative margin resulting in resection of the ipsilateral neurovascular bundle (Schlomm et al., 2012; von Bodman et al., 2013). In one study, it was noted that it took 5 cryostats with 2 pathologists and 4 technicians to perform one case in about 35 minutes, which is not practical for most laboratories. The technique includes a low false-negative and false-positive rate compared with the permanent sections of the same slides. However, in two studies in which a frozen-section margin was positive in the region of the neurovascular bundle and the bundle was removed, only 23% to 25% of the bundles showed residual cancer. Arguments posited in support of this procedure are (1) without the frozen sections most of these patients would have had the bundles resected because of preoperative high-risk characteristics; and (2) the overall sum of saved neurovascular bundles was markedly higher than the unnecessary secondary wide excisions (Schlomm et al., 2012; von Bodman et al., 2013). The preponderance of studies shows that the distance from tumor to ink does not affect the risk for recurrence, although one conflicting study exists (Bong et al., 2009; Emerson et al., 2005; Epstein, 1990; Epstein and Sauvageot, 1997; Lu et al., 2012). **Factors that can aid in the clinician's decision as to whether or not to administer adjuvant radiation therapy are the extent of positive margins and the grade of the tumor at the margins, and these factors have been shown to be prognostic** (Brimo et al., 2010; Cao et al., 2010; Chuang and Epstein, 2008; Huang et al., 2013; Kates et al., 2016; Shikanov et al., 2009; van Oort et al., 2010).

Positive margins also may arise as a result of the surgical transection of intraprostatic tumor (intraprostatic incision); although also referred to as *capsular incision,* this term is not recommended, as there is no prostatic capsule. The reported incidence of intraprostatic incision ranges from 1.3% to as high as 71% (Epstein, 2001). In my opinion, much of this variation relates to the difficulties described in the preceding text in recognizing EPE. If an extraprostatic tumor associated with a desmoplastic stromal response at a margin is misdiagnosed as organ confined, it will be misclassified as a positive margin because of intraprostatic incision. The other relatively frequent site of intraprostatic incision is in the regions of the neurovascular bundles, where the urologist attempts to preserve the bundle for potency, yet cuts into the prostate. Only if both tumor and benign glands are transected in the same area and are present at the inked margin do I diagnose a positive margin as a result of intraprostatic incision. **Intraprostatic incision is associated with an increased risk for postoperative progression equivalent to that associated with focal EPE and a positive margin** (Chuang and Epstein, 2008)**.**

In a multivariate analysis, Gleason grade, EPE, and margins of resection are strong independent predictors of biochemical progression.

Tumor Volume.

There are conflicting studies regarding whether or not tumor volume independently predicts post–radical prostatectomy progression after grade and pathologic stage are determined, with most of the larger series not showing prognostic significance (Epstein, 2001). Despite this fact, the International Society of Urological Pathology recommends that some objective measurement of tumor volume be reported in radical prostatectomy specimens (van der Kwast et al., 2011). The Society's rationale is that tumor volume is recorded for cancers in other organ systems. Because tumor volume is not an independent predictor and will in general not affect subsequent therapy, it is my recommendation that if one feels obliged to report a radical prostatectomy tumor, then the simplest and fastest method should be used, such as a rough estimate of the overall percentage of the prostate involved by the tumor or maximum dimension of tumor.

Perineural and Vascular Invasion.

The finding of perineural invasion in a radical prostatectomy specimen is very common, is not prognostic, and should not be included in the pathology

report. Vascular invasion is uncommonly identified in radical prostatectomy specimens, seen in 7% of tumors smaller than 4 cc (most tumors seen today at radical prostatectomy are smaller than 2 cc) (McNeal and Yemoto, 1996b). Vascular invasion correlates with other adverse findings (i.e., EPE, grade, margins, tumor volume), yet still offers independent prognostic information beyond those of routinely noted findings (Baydar et al., 2008; Epstein, 2001).

Adenocarcinoma With Treatment Effect

One of the problems with evaluating carcinomas that have been treated with hormone therapy is that the grade often appears artifactually higher (Smith and Murphy, 1994). **Pathologists should not assign a Gleason score to carcinomas with treatment effect.** However, if other areas of the tumor do not show a pronounced hormone effect, these areas can be Gleason graded. It has been demonstrated that finasteride does not alter the histology of either benign or malignant tissue (Baydar et al., 2008; Epstein, 2001).

Radiated adenocarcinoma of the prostate may either show no recognizable difference from nonradiated cancer or may show the effects of radiation damage. **When signing out postradiotherapy biopsies, they should be diagnosed as either: (1) benign prostate tissue with radiation effect; (2) cancer without treatment effect (a Gleason grade is assigned); or (3) cancer showing treatment effect (no Gleason grade assigned). The latter diagnosis is associated with an equivalent prognosis to a noncancerous diagnosis** (Crook et al., 2009). Radiation alters the histologic features of benign prostate tissue so that it may mimic prostate cancer (Bostwick et al., 1982). Radiation atypia in benign prostate glands may persist for a long time (up to 72 months) after the initial treatment, resulting in a significant pitfall in evaluating prostate biopsy specimens (Magi-Galluzzi et al., 2003). If clinicians are aware of such treatment, this information should be provided to the pathologist.

Cryotherapy or HIFU treatment results in infarction of benign and neoplastic prostate tissue. If residual cancer is seen following these therapies, there is no treatment affect present and a Gleason score can be assigned.

Subtypes of Prostate Adenocarcinoma

Mucinous adenocarcinomas of the prostate gland behave like usual prostate carcinomas, including a propensity to develop bone metastases with advanced disease (Epstein and Lieberman, 1985; Ro et al., 1990). **Mucinous adenocarcinoma of the prostate treated by radical prostatectomy is not more aggressive than nonmucinous prostate cancer** (Osunkoya et al., 2008; Samaratunga et al., 2017). Even in ordinary adenocarcinomas of the prostate without light microscopic evidence of neuroendocrine differentiation, almost one-half show neuroendocrine differentiation on evaluation with immunohistochemistry for multiple neuroendocrine markers (di Sant'Agnese, 1992). Most studies do not demonstrate a convincing relationship between the extent of neuroendocrine differentiation in ordinary prostate cancer and prognosis. Many small cell carcinomas of the prostate are identical to small cell carcinomas of the lung (Tetu et al., 1989). In approximately 50% of the cases, the tumors are mixed small cell carcinoma and adenocarcinoma of the prostate. There are cases in which it can be difficult to distinguish between small cell carcinoma and high acinar adenocarcinoma of the prostate, in part resulting from overlap cases with usual acinar carcinoma transdifferentiating to small cell carcinoma (Epstein et al., 2014). **The average survival of patients with small cell carcinoma of the prostate is less than 1 year.** There is no difference in prognosis between patients with pure small cell carcinoma and those with mixed glandular and small cell carcinomas. Small cell carcinomas are not assigned a Gleason grade.

Between 0.4% and 0.8% of prostatic adenocarcinomas arise from prostatic ducts (Christensen et al., 1991; Epstein and Woodruff, 1986). In about 5% of prostatic carcinomas, tumors showing both ductal and acinar differentiation are found. When prostatic duct adenocarcinomas arise in the large primary periurethral prostatic ducts, they may grow as an exophytic lesion into the urethra, most commonly in and around the verumontanum, and this gives rise to either obstructive symptoms or hematuria. Tumors arising in the more peripheral prostatic ducts may present similar to ordinary (acinar) adenocarcinomas of the prostate and may be diagnosed on needle biopsy (Brinker et al., 1999). Tumors are often underestimated clinically because rectal examination findings and serum PSA levels may be normal. **Most prostatic duct adenocarcinomas should be regarded as Gleason pattern 4 because of their shared cribriform**

morphologic features with acinar adenocarcinoma Gleason score 8 and a similar prognosis (Brinker et al., 1999). Exceptions are the PIN-like ductal adenocarcinoma, which is assigned a Gleason pattern 3 (Tavora and Epstein, 2008) and the ductal adenocarcinoma with comedonecrosis, which is assigned a Gleason pattern 5. There are conflicting studies regarding whether or not a ductal adenocarcinoma component that is assigned a Gleason pattern 4 (or pattern 5 if accompanied by comedonecrosis) is associated with a poorer prognosis than a comparably graded acinar carcinoma (Samaratunga et al., 2010; Seipel et al., 2013). **Pure primary squamous carcinoma of the prostate is rare and is associated with poor survival** (Parwani et al., 2004). These tumors develop osteolytic metastases and do not respond to hormonal therapy. More commonly, squamous differentiation occurs in the primary and metastatic deposits of adenocarcinomas that have been treated with estrogen therapy. Sarcomatoid carcinomas (carcinosarcomas) have also been reported within the prostate and have a dismal prognosis (Hansel and Epstein, 2006).

Mesenchymal Tumors

Sarcomas of the prostate account for 0.1% to 0.2% of all malignant prostatic tumors (Hansel et al., 2007). Rhabdomyosarcomas are the most frequent mesenchymal tumor within the prostate and are seen almost exclusively in childhood. Leiomyosarcomas are the most common sarcomas involving the prostate in adults (Cheville et al., 1995). A spindle cell lesion that can occur at any age and can closely simulate a leiomyosarcoma is an inflammatory myofibroblastic tumor, which may occur soon after TUR or without a history of TUR (Montgomery et al., 2006). There are also mesenchymal tumors of the prostate arising from the unique prostatic specialized stroma. These lesions range from prostatic stromal tumors of uncertain malignant potential (STUMP) to prostatic stromal sarcomas. On histologic examination, these lesions are variable; one subtype resembles a tumor seen in the breast and is termed *phyllodes tumor of the prostate* (Herawi and Epstein, 2006). Although most cases of prostatic STUMP do not behave in an aggressive fashion, occasional cases have been documented to recur rapidly after resection; cases with mixed STUMP and sarcomas exist, and a few STUMP have progressed to stromal sarcoma. **Although many STUMP may behave in an indolent fashion, their unpredictability in a minority of cases and the lack of correlation between different histologic patterns of STUMP and sarcomatous dedifferentiation**

warrant close follow-up and consideration of definitive resection in younger individuals. Stromal sarcomas have the potential for metastatic behavior.

Urothelial Carcinoma

Primary urothelial carcinoma of the prostate without bladder involvement accounts for 1% to 4% of all prostate carcinomas (Sawczuk et al., 1985). Primary urothelial carcinomas of the prostate show a propensity to infiltrate the bladder neck and the surrounding soft tissue such that more than 50% of patients present with stage T3 or T4 tumors (Greene et al., 1976). Twenty percent of patients present with distant metastases, with the bone (predominantly osteolytic), the lung, and the liver being the most common sites.

More commonly, urothelial carcinoma involves prostatic ducts and acini in patients with a history of carcinoma in situ (CIS) of the bladder who have been treated for a period of months to years with intravesical topical chemotherapy (Mahadevia et al., 1986; Njinou Ngninkeu et al., 2003; Schellhammer et al., 1977; Wood et al., 1989). Between 35% and 45% of cystoprostatectomies performed for urothelial carcinoma contain prostatic involvement. However, this number is dependent on the amount of histologic sampling of the prostate tissue and may be much higher in completely mapped specimens. If cystoprostatectomy is performed and only intraductal urothelial carcinoma is present, the prostatic involvement does not worsen the prognosis, which is determined by the stage of the bladder tumor (Esrig et al., 1996). Intraductal urothelial carcinoma of the prostate appears to involve the prostate by direct extension from the overlying urethra, which is usually involved by CIS. Intraductal and infiltrating urothelial carcinoma involving the prostate tends to be seen in higher-stage bladder tumors, in which the patients have a poor prognosis attributable to either advanced bladder or prostatic disease. A minority of these cases will have low-stage bladder tumor and a poorer prognosis, demonstrating the adverse effect of prostatic stromal infiltration (Esrig et al., 1996). **Urothelial carcinoma involving the prostate is substaged into pT1 when invasive carcinoma involves the suburethral tissue or pT2 when there is CIS involving prostatic acini with prostatic stromal invasion.** It is not clear how to report the staging of both the bladder urothelial carcinoma and prostatic involvement in cystoprostatectomy specimens. I report the findings in both the bladder and prostate, assigning separate stages for each organ. Alternatively, one can just report the bladder or prostatic stage, depending which is higher, and then describe the extent of disease in the other organ. **Extensive sampling of the periurethral area in cystoprostatectomy specimens performed for urothelial carcinoma is necessary to identify and to evaluate the prostate for urothelial carcinoma.**

Finally, one may find direct invasion from bladder urothelial carcinoma into the stroma of the prostate. The distinction between poorly differentiated urothelial carcinoma and poorly differentiated adenocarcinoma of the prostate can be difficult histologically and is compounded by the difficulty in distinguishing between a bladder and prostate primary clinically. Some cases of extensive high-grade prostatic adenocarcinoma involving the bladder neck are labeled as a “bladder tumor” by the urologist, which can contribute to a pathologic misdiagnosis of urothelial carcinoma. Approximately 95% of poorly differentiated prostatic adenocarcinomas show PSA staining, although it may be focal (Chuang et al., 2007). In some cases of poorly differentiated prostatic adenocarcinomas, there may be weak or negative PSA staining, where the tumor reacts to a greater degree with newer prostate-specific markers, including p501S (prostein) and NKX 3.1 (Chuang et al., 2007). Although CK7 and CK20 are more frequently seen in urothelial carcinoma as compared with adenocarcinoma of the prostate, they may also be positive in adenocarcinoma of the prostate. The most sensitive and specific marker that labels urothelial carcinoma and not prostate carcinoma is GATA3 (80%) (Chang et al., 2012; Higgins et al., 2007). Less sensitive markers include uroplakin and thrombomodulin (49% to 69% sensitivity) and p63 and high-molecular-weight cytokeratin (60% to 70% sensitivity) (Chuang et al., 2007).

Miscellaneous Malignant Tumors

Primary prostatic lymphoma without lymph node involvement appears to be much less common than secondary infiltration of the prostate (Bostwick and Mann, 1985). The most common form of leukemic involvement of the prostate is that of chronic lymphocytic leukemia, although monocytic, granulocytic, and lymphoblastic leukemias have also been found in the prostate (Dajani and Burke, 1976).

Key Points

- LGPIN should not be commented on in diagnostic reports, because the diagnosis is not reproducible among pathologists and it lacks clinical significance.
- For patients diagnosed with HGPIN on one core of an extended initial core sampling, repeat biopsy within the first year is unnecessary in the absence of other clinical indicators of cancer. The follow-up for biopsies with two or more cores involved by HGPIN is the same as for an atypical biopsy.
- Regardless of the serum PSA level, the risk for cancer after an atypical biopsy suspicious for carcinoma is approximately 40%. Given that 80% of the cancers detected on repeat biopsy are Gleason score 6, some urologists may choose to follow up with serum or urine tests, imaging, and only in some cases perform repeat biopsy with relative increased sampling of the atypical site. Other urologists, recognizing that 20% of cancers on repeat biopsy are Gleason score 7 or higher, may routinely recommend repeat biopsy after an atypical diagnosis.
- Cases diagnosed as atypical have the highest likelihood of being changed on expert review. Urologists should consider sending such cases for consultation to attempt to resolve the diagnosis as either definitively benign or malignant before subjecting the patient to repeat biopsy.
- Tumor volume measured in the radical prostatectomy specimen does not independently predict postsurgical progression after the grade, the pathologic stage, and the margins are considered.
- Gleason grade, whether it is assessed on needle biopsy, TUR, or radical prostatectomy specimens, remains one of the most influential prognostic factors.
- The new Grade Groups for prostate adenocarcinoma (based on Gleason's original grading system following multiple significant modifications) provide a simpler, more intuitive, and better prognostic grading system.

Diagnosis and Staging of Prostate Cancer

Stacy Loeb MD, MSc, James A. Eastham MD

Prostate cancer rarely causes symptoms at an early stage. The presence of symptoms suggests locally advanced or metastatic disease. Manifestations of locally advanced prostate cancer include obstructive urinary symptoms; ureteral obstruction causing renal failure, hematospermia or decreased ejaculate volume; and, rarely, impotence. Manifestations of metastatic disease include bone pain, pathologic fractures, anemia, and lower extremity edema; less common are malignant retroperitoneal fibrosis, paraneoplastic syndromes, disseminated intravascular coagulation (DIC), and paralysis. Locally advanced and metastatic disease are uncommon presentations because of widespread screening with prostate-specific antigen (PSA) testing and digital rectal examination (DRE). A histologic diagnosis of prostate cancer is typically made by prostate needle biopsy with guidance from ultrasound and/or magnetic resonance imaging (MRI) before any symptoms develop.

After a diagnosis of prostate cancer, the goal of staging is the accurate determination of disease extent and risk for management decisions and prognostication. In addition to PSA level and DRE, the pathologic features on prostate biopsy (grade and volume of cancer) help inform management decisions. Imaging studies also may be used during the staging process to evaluate the locoregional extent of disease and/or to rule out metastases.

This chapter reviews diagnostic and staging modalities for prostate cancer.

Diagnosis

Screening

General Concepts of Screening

Screening refers to testing for disease in healthy, asymptomatic populations, whereas *diagnosis* is the identification of disease among individuals with signs or symptoms. The principal goal of screening is to improve overall health outcomes by identifying and treating disease at an earlier stage. Despite the common misperception that early diagnosis through screening is invariably beneficial, it also has the potential for harm (Welch, 2004). Strong evidence indicates that prostate cancer screening reduces the rates of advanced disease at the time of diagnosis (Aus et al., 2007; van der Cruijsen-Koeter et al., 2006), and more recent data show that it also reduces prostate cancer mortality (Hugosson et al., 2010; Schröder et al., 2012), but controversy exists regarding the balance of benefit and harm (Barry, 2009; U.S. Preventive Services Task Force [USPSTF], 2008). The precise balance of benefits and harms is highly dependent on the patient's characteristics and preferences (Heijnsdijk et al., 2012).

During the PSA era, the mortality rate from prostate cancer has declined by more than 40% (Surveillance, Epidemiology, and End Results [SEER] program), along with a 75% reduction in the proportion of advanced-stage disease at diagnosis. It was estimated by mathematical modeling that PSA screening could have accounted for 45% to 70% of this reduction in prostate cancer mortality in the United States (Etzioni et al., 2008). However, randomized trials comparing the disease-specific outcomes of men who are screened and those who are not represent the highest level of evidence for screening.

Randomized Trials

The Prostate, Lung, Colon, and Ovary (PLCO) trial of the National Cancer Institute (NCI) and the European Randomized Trial of Prostate Cancer Screening (ERSPC) were initiated in 1993 to compare prostate cancer–specific mortality (primary end point) between men who were randomized to screening and those who were not (Andriole et al., 2004; Auvinen et al., 1996; de Koning et al., 2002; Schröder, 2003). Reductions in high-grade cancer and locally advanced/metastatic disease with serial screening were reported in the ERSPC

(Aus et al., 2007; van der Cruijsen-Koeter et al., 2006), and a 21% reduction in prostate cancer–specific mortality among those screened compared with controls at a median follow-up of 13 years (Schröder et al., 2014). However, in the ERSPC it was estimated that to prevent one prostate cancer death would require inviting for screening 781 men and diagnosing an additional 27 men at 13 years (Schröder et al., 2014). By comparison, there was no difference in prostate cancer mortality between the screened and control arms of the PLCO at a median follow-up of 13 years (Andriole et al., 2012). Further, the disparate findings between the studies may result from high rates of screening in the control arm of the PLCO before and during the trial (contamination) (Shoag et al., 2016) and lower power to detect a mortality difference given that the PLCO had approximately threefold fewer events than the ERSPC (Barry, 2009).

These randomized trials emphasize the potential for overdiagnosis (detection of cancers that would have otherwise remained undetected) and overtreatment of prostate cancer with screening. Overtreatment is especially concerning among older men (older than 65 years of age), for whom treatment was associated with minimal benefit in a randomized trial of surgery versus watchful waiting (Bill-Axelson et al., 2011). Given that the average age at diagnosis today is approximately 66 years, the risk for overtreatment is high (National Cancer Institute, 2016).

Specialty Group Recommendations

Professional groups have published statements and guidelines on prostate cancer screening (Lim et al., 2008; Lin et al., 2008; National Comprehensive Cancer Network, 2014; U.S. Preventive Services Task Force, 2008). In 2008, the USPSTF concluded that the evidence was insufficient to assess the balance of benefit and harm of screening among men 75 years of age or younger, whereas screening was not recommended for men 75 years of age or older. In 2011, the USPSTF issued a grade D draft recommendation against prostate cancer screening, which was finalized in 2012. In 2017, the USPSTF issued a revised recommendation (finalized in 2018) with a grade of “C” for PSA-based prostate cancer screening for men 55 to 69 years of age. They recommend shared decision making for men 55 to 69 years of age and do not recommend screening for men 70 years of age and older. The USPSTF notes that the increased use of active surveillance (observation with selective delayed treatment) for low-risk prostate cancer has reduced the risks associated with screening.

The American College of Preventive Medicine determined there is insufficient evidence to recommend routine population screening with PSA and DRE (Lim et al., 2008) and suggests that men should be given information about benefits and harms to make an informed decision. The American Cancer Society recommends that men with at least a 10-year life expectancy should have an opportunity to make an informed decision with their health care provider about prostate cancer screening beginning at 50 years of age for average-risk men and before 50 years of age for groups at higher risk (American Cancer Society, 2016). Previously, the American Urological Association (AUA) recommended annual prostate cancer screening beginning at 50 years of age for average-risk men and earlier for men at higher risk (positive family history or black race). In 2013 the AUA issued updated guidelines that recommend shared decision making about screening for men 55 to 69 years of age (American Urological Association, 2013a; reviewed and confirmed 2015). Based on the ERSPC, they suggest that a 2-year screening interval would preserve the benefits and reduce harms from screening. The National Comprehensive Cancer Network recommends starting a risk to benefit discussion and offering baseline PSA screening at 45 years of age with the frequency of follow-up testing based on PSA test results (1- to 4-year intervals). Similarly, the Memorial Sloan Kettering Cancer Center guidelines recommend performing a baseline PSA test between 45 and 49 years of age and using PSA levels to guide screening intervals (Memorial Sloan Kettering Cancer Center, 2013). The European Association of Urology also recommends a risk-adapted approach based on the initial PSA level for well-informed men with good performance status and a 10- to 15-year life expectancy (Heidenreich et al., 2013). For example, if the PSA level is greater than 1 ng/mL at 40 years of age or >2 ng/mL at 60 years of age, screening should be done at 2-year intervals, whereas longer intervals up to 8 years can be used for men with lower levels. Overall, the appropriate age to start and discontinue screening (Catalona et al., 2006; Ross et al., 2005; Schaeffer et al., 2009) and the appropriate interval between screens will continue to be a matter of debate as additional randomized trials to address these questions are logistically unlikely (Carter et al., 1997a; Hugosson et al., 2003b; Ross et al., 2000).

Despite the controversy associated with prostate cancer screening, opportunistic prostate cancer screening is highly prevalent in the United States (Chan et al., 2006; Lu-Yao et al., 2003; Ross et al., 2004; Schwartz et al., 2004; Sirovich et al., 2003; Walter et al., 2006). **Men who present for periodic health examinations should be made aware of the benefits and risks of PSA screening so that they can make an informed decision whether to be**

screened.

Diagnostic Modalities

Digital Rectal Examination

Before the availability of PSA testing, physicians relied solely on DRE for early detection of prostate cancer (Catalona et al., 1994b; Cooner et al., 1990; Ellis et al., 1994; Okotie et al., 2007; Schröder et al., 1998; Vis et al., 2001). DRE has only fair reproducibility in the hands of experienced examiners (Smith and Catalona, 1995) and misses a substantial proportion of early cancers (Catalona et al., 1994b; Cooner et al., 1990; Ellis et al., 1994). It has been suggested that the value of DRE for screening at PSA levels below 3.0 ng/mL is limited (Schröder et al., 1998; Vis et al., 2001). **Because of the risk for prostate cancer among men with abnormalities on DRE and the simplicity of the examination, most urologists use PSA and DRE together for prostate cancer detection.**

Further, **PSA testing improves the positive predictive value (PPV) of DRE for cancer** (Schröder et al., 1998). The PPV of DRE ranged from 4% to 11% in men with PSA levels of 0 to 2.9 ng/mL and from 33% to 83% in men with PSA levels of 3 to 9.9 ng/mL or greater (Schröder et al., 1998).

Overall, when DRE and PSA tests are used in prostate cancer screening, detection rates are higher with PSA testing than with DRE and highest with the tests together (Catalona et al., 1991). Because DRE and PSA tests do not always detect the same cancers (Okotie et al., 2007), the tests are complementary. In addition, many contemporary nomograms incorporate DRE findings to provide more personalized projections of prostate cancer risk (Thompson et al., 2006).

Prostate-Specific Antigen

PSA is a member of the human kallikrein gene family, is secreted in high concentrations (milligrams per milliliter) into seminal fluid, and circulates in bound (complexed) and unbound (free) forms that can be measured using assays approved by the U.S. Food and Drug Administration (FDA).

Factors Influencing Prostate-Specific Antigen.

Serum PSA levels vary with age, race, and prostate volume. African-Americans without prostate cancer have higher PSA values than whites (Fowler et al., 1999;

Morgan et al., 1996). PSA increases 4% per milliliter of prostate volume; and 30% and 5% of the variance in PSA levels can be accounted for by prostate volume and age, respectively (Oesterling et al., 1993).

PSA expression is strongly influenced by androgens (Henttu et al., 1992; Young et al., 1991). Serum PSA becomes detectable at puberty with increasing levels of luteinizing hormone and testosterone (Vieira et al., 1994). In hypogonadal men with low testosterone levels, serum PSA level may be low because of decreased expression and may not reflect the presence of prostate disease such as cancer (Morgentaler et al., 1996).

Metabolic factors can influence serum PSA levels. Obese men have slightly lower PSA levels than nonobese men (Baillargeon et al., 2005), possibly because of hemodilution (Bañez et al., 2007). Statin use may reduce PSA levels (Hamilton et al., 2008).

Another factor that can influence PSA levels includes the assay that is used in the measurement, potentially resulting in pseudo-acceleration or pseudo-deceleration if different assays are used for serial measurements (Loeb et al., 2008a). Recent studies have suggested that genetic factors may influence PSA levels and have raised the possibility of genetically adjusted PSA values in the future (Gudmundsson et al., 2010; Helfand et al., 2013).

Overall, the presence of prostate disease (prostate cancer, benign prostatic hyperplasia [BPH], and prostatitis) is the most important factor affecting serum PSA levels (Dalton, 1989; Ercole et al., 1987; Nadler et al., 1995; Wang et al., 1981). Although PSA elevations may indicate the presence of prostate disease, not all men with prostate disease have elevated PSA levels, and PSA elevations are not specific for cancer.

It is postulated that serum PSA elevations occur from disruption of the normal prostatic architecture, allowing PSA to gain access to the circulation. This can occur in the setting of prostate disease (BPH, prostatitis, prostate cancer) and with prostate manipulation (e.g., prostate massage, prostate biopsy, transurethral resection) (Klein and Lowe, 1997). Although DRE can lead to slight increases in serum PSA level, the resultant change in PSA values falls within the error of the assay and rarely causes false-positive test results (Crawford et al., 1992).

Studies examining the effect of ejaculation on serum PSA have reported conflicting results (Heidenreich et al., 1997; Herschman et al., 1997; Kirkali et al., 1995; Simak et al., 1993; Stenner et al., 1998; Tchetgen et al., 1996; Yavascaoglu et al., 1998). A repeat PSA test after 48 hours of sexual abstinence may be helpful for interpreting serum PSA levels that are minimally elevated.

Prostate-directed treatments (for BPH or prostate cancer) can lower serum PSA levels by decreasing the volume of prostatic epithelium available for PSA production and by decreasing the amount of PSA produced per cell (Shingleton et al., 2000).

5α-Reductase inhibitors that are used for BPH treatment have been shown to lower PSA levels, including both type 2 isoenzyme inhibitors (finasteride) and dual type 1 and 2 isoenzyme inhibitors (dutasteride) (Guess et al., 1993; Roehrborn et al., 2002). Finasteride 1 mg (Propecia) used for male pattern hair loss (androgenic alopecia) results in the same decline in serum PSA levels as the 5-mg dosage used for the treatment of BPH (D'Amico and Roehrborn, 2007).

Men initiating treatment with 5α-reductase inhibitors should first have a baseline PSA measurement and should be followed with serial measurements. Although the PSA level is often multiplied by 2 to estimate the “true” PSA level of a patient who has been taking a 5α-reductase inhibitor for 12 months or more (Andriole et al., 1998), the PSA response to finasteride treatment can be highly variable (Marks et al., 2006). It has been suggested that the PSA should instead be multiplied by a factor of 2.3 after 2 years and 2.5 after 7 years of treatment (Etzioni et al., 2005; Thompson et al., 2007; Walsh, 2008). Because this “moving target” can complicate the use of PSA levels in daily clinical practice, some have recommended using the PSA nadir on finasteride as the new baseline and performing a biopsy for subsequent PSA increases (Morgentaler, 2007).

Surgical therapy for BPH can lead to reductions in the serum PSA level (Shingleton et al., 2000) and “reset” the PSA baseline to a variable extent by removing the main contributor to PSA production (transition zone).

Finally, prostate cancer treatments (medical or surgical) such as manipulation of the hormonal axis (e.g., luteinizing hormone–releasing hormone agonists, orchiectomy), radiation therapy, radical prostatectomy, and other ablative techniques (e.g., cryotherapy) lead to reductions in PSA levels.

The interpretation of PSA values should always take into account age, the presence of urinary tract infection or prostate disease, recent diagnostic procedures, and prostate-directed treatments.

Clinical Use for Diagnosis.

The initial assays for PSA that were approved by the FDA in 1994 for early detection of prostate cancer detected both free PSA (fPSA) and PSA complexed (cPSA) to α_1-antichymotrypsin (ACT). Thus measurement of fPSA and cPSA by these assays is generally referred to as the serum PSA level (Smith et al., 1996).

Specific assays that detect fPSA alone and PSA complexed to ACT alone have been evaluated and approved for prostate cancer detection (see later discussion).

It is now well established that the use of PSA increases the detection of prostate cancers that are more likely to be organ-confined when compared with detection without PSA (Chodak et al., 1989; Hoedemaeker et al., 2000; Mueller et al., 1988; Rietbergen et al., 1999; Thompson et al., 1987). Observational studies and randomized trials have shown that both the future risk for prostate cancer and the chance of finding cancer on a prostate biopsy increase incrementally with the serum PSA level (Andriole et al., 2005; Brawer et al., 1992; Catalona et al., 1991, 1994a; Fang et al., 2001; Gann et al., 1995; Labrie et al., 1992; Lilja et al., 2007; Loeb et al., 2006; Thompson et al., 2004; Whittemore et al., 2005).

Gann et al. (1995) were first to demonstrate the association between the baseline PSA level and subsequent prostate cancer detection, which has been verified by others (Antenor et al., 2004; Fang et al., 2001; Loeb et al., 2006; Whittemore et al., 2005). A study from the Malmo Preventive Project confirmed that baseline PSA measurements in the 40s predict the risk for prostate cancer metastasis and death more than 25 years later (Vickers et al., 2013).

In addition to predicting future risk, PSA is directly associated with the present risk for prostate cancer. The probability of detecting prostate cancer on biopsy increases directly with PSA across the full spectrum of PSA levels (Table 152.1) (Thompson et al., 2004).

TABLE 152.1

Prostate Cancer Detection as a Function of Serum Prostate-Specific Antigen Level and Digital Rectal Examination Findings in Contemporary Series

PSA LEVEL (ng/ml)	DRE FINDINGS[a]	CANCER DETECTION RATE (%)[b]	CANCER YIELD ON BIOPSY (%)[c]	RATE OF HIGH-GRADE CANCER ON BIOPSY (%)[d]

	+	14–38	55–63	20.6

[a] −, DRE nonsuspicious for cancer; +, DRE suspicious for cancer.

[b] Cancer detection rate is the number of cancers found in those screened (total number of detected cancers divided by total number of men screened).

[c] Cancer yield is the total number of cancers detected divided by the total number of men undergoing a biopsy. For digital rectal examination (DRE) (−) this indicates the positive predictive value of prostate-specific antigen (PSA) at a specified level when the DRE is not suspicious for cancer; for DRE (+) it is the positive predictive value of a suspicious DRE when the PSA is at a specified level.

[d] Gleason score of 7 or more.

In summary, **both PSA and DRE are used to assess prostate cancer risk in conjunction with other clinical factors.**

Triggers for Biopsy.

The choice of a PSA threshold for recommending a prostate biopsy is controversial (Carter, 2004; Catalona et al., 1994a; Gann et al., 1995; Nadler et al., 2005; Thompson et al., 2005) and has previously been reviewed (Schröder et al., 2008). Gann et al. (1995) pointed out that “dichotomization of PSA results into normal and abnormal obscures important information contained in levels below the usual cutoff.” Data from the Prostate Cancer Prevention Trial clearly show that the risk for prostate cancer is continuous as PSA increases (Thompson et al., 2005). Some investigators have recommended against referring to PSA as "elevated" or "abnormal."

The use of higher PSA thresholds risks missing important cancers during the window for cure, whereas the use of lower thresholds increases the proportion of unnecessary biopsies and overdiagnosis. Although PSA was initially approved using 4 ng/mL as the upper limit of normal, many clinicians subsequently adopted lower thresholds (2.5 to 3 ng/mL) to trigger a biopsy. In the ERSPC, most centers used a threshold of 3 ng/mL to trigger a prostate biopsy. However, a higher cutoff, such as 10 ng/mL, was recently suggested to reduce the potential harms for men older than 70 years of age (American Urological Association, 2013b).

A PSA level that is considered suspicious for prostate cancer should be remeasured before performing a prostate biopsy because of fluctuations in PSA levels that could create false-positive elevations (Eastham et al., 2003). However, according to the Choosing Wisely Campaign, empiric antibiotics should not be given to patients exclusively for an elevated PSA without any other urinary symptoms (American Urological Association, 2013b).

Numerous organizations now recommend using PSA together with other methods of risk assessment, such as family history, race, and DRE findings (Murphy et al., 2014).

Prostate-Specific Antigen Derivatives and Molecular Forms

Numerous variations on PSA-based screening have been proposed to improve test performance, including the adjustment of the PSA level for total prostate volume (PSA density [PSAD]) (Babaian et al., 1990; Bazinet et al., 1994; Benson et al., 1992a, 1992b; Catalona et al., 2000b; Djavan et al., 2002; Egawa et al., 2002; Gjengstø et al., 2005; Littrup et al., 1991; Naya et al., 2002; Rommel et al., 1994; Veneziano et al., 1990) or transition zone volume (Djavan et al., 1999; Gjengstø et al., 2005; Singh et al., 2004; Taneja et al., 2001) and the evaluation of rate of change in PSA (PSA velocity [PSAV]) (Berger et al., 2005, 2007; Carter et al., 1992b; D'Amico et al., 2004, 2005; Eggener et al., 2008; Fang et al., 2002; Fowler et al., 2000; Loeb et al., 2007a, 2008b; Roobol et al., 2004; Schröder et al., 2006; Smith and Catalona 1994). The discovery that PSA circulates in both bound (complexed) and unbound (free) forms and development of assays to measure these forms separately have resulted in investigation of their use for prostate cancer detection (Gretzer and Partin, 2003; Lilja, 1997, 2003; McCormack et al., 1995; Polascik et al., 1999), and this topic has been reviewed previously (Jansen et al., 2009).

Volume-Based Prostate-Specific Antigen Parameters.

Distinguishing between men with PSA elevations driven by BPH or cancer is difficult because PSA is not specific for cancer and the prevalence of BPH is high. Volume-based PSA parameters (with prostate volume typically determined by ultrasonography or more recently with magnetic resonance imaging) have been evaluated to reduce confounding from BPH. These include PSA divided by prostate volume (PSAD), complexed PSAD (cPSA divided by prostate volume), and PSA transition zone density (PSA divided by transition zone volume) (Babaian et al., 1990; Bazinet et al., 1994; Benson et al., 1992a, 1992b; Catalona et al., 2000b; Djavan et al., 1999, 2002; Gjengstø et al., 2005; Littrup et al., 1991; Naya et al., 2002; Rommel et al., 1994; Veneziano et al., 1990).

Benson et al. (1992a, 1992b) suggested that adjusting PSA for prostate size—by dividing PSA by prostate volume (PSAD)—could help distinguish between PSA elevations caused by BPH and those caused by prostate cancer. A direct relationship between PSAD and the chance of cancer has been documented (Bazinet et al., 1994; Rommel et al., 1994; Seaman et al., 1993), and a PSAD of 0.15 or greater was proposed for recommending prostate biopsy in men with PSA levels between 4 and 10 ng/mL and normal DRE (Bazinet et al., 1994; Seaman et al., 1993). The usefulness of PSAD in prostate cancer detection has not been confirmed in all studies (Cooner, 1994; Taneja et al., 2001). An advantage of PSAD is that it has been directly associated with prostate cancer aggressiveness (Carter et al., 2002; Kundu et al., 2007) and therefore is currently used to help assess eligibility for active surveillance among men with prostate cancer (Bul et al., 2013; Tseng et al., 2010). PSA has been adjusted for the transition zone volume (Kalish et al., 1994), the prostatic region that is the major determinant of serum PSA in men without prostate cancer (Lepor et al., 1994).

In general, although PSAD and its associated measures are imperfect predictors of cancer, they represent an additional method of risk assessment with potential utility for counseling men with intermediate PSA levels (4 to 10 ng/mL) regarding the need for prostate biopsy (Benson and Olsson, 1994) or repeat biopsy if PSA is persistently elevated (Keetch et al., 1996). PSAD is also used for risk stratification and to determine eligibility for active surveillance among men with newly diagnosed prostate cancer (Loeb et al., 2015).

Prostate-Specific Antigen Velocity.

Short-term fluctuations in PSA can occur between measurements in the presence or absence of prostate cancer, primarily as a result of physiologic variation

(Carter et al., 1992a, 1995; Eastham et al., 2003; Prestigiacomo and Stamey, 1996; Riehmann et al., 1993). However, the rate of change in PSA (PSAV)—PSA corrected for the elapsed time between measurements (Carter et al., 1992b)—is associated with the risk for prostate cancer (Berger et al., 2005, 2007; Carter et al., 1992b; D'Amico et al., 2004, 2005; Eggener et al., 2008; Loeb et al., 2007a, 2007b, 2008b; Roobol et al., 2004; Sengupta et al., 2005; Schröder et al., 2006; Smith and Catalona, 1994; Vickers et al., 2009). Using frozen sera to measure PSA years before diagnosis, Carter et al. (1992b) showed that a PSAV greater than 0.75 ng/mL/year was a specific marker for the presence of prostate cancer in men with PSA levels between 4 and 10 ng/mL. Other studies demonstrated that men with prostate cancer have more rapid rises in PSA levels than men without prostate cancer (Carter et al., 1995; Loeb et al., 2008c; Raaijmakers et al., 2004b; Smith and Catalona, 1994; Thompson et al., 2004). It was later shown that PSAV might also be useful for prostate cancer detection among men with PSA levels below 4.0 ng/mL (Carter et al., 2006; Loeb et al., 2007b). Some investigators have suggested the use of lower PSAV thresholds of 0.4 ng/mL/year for men with lower total PSA (tPSA) levels (Loeb et al., 2007b; Moul et al., 2007).

Some studies have failed to demonstrate the value of PSAV for prostate cancer prediction beyond that of a single PSA measurement (Roobol et al., 2004; Vickers et al., 2009). Differences among studies could be a result of the method used to calculate PSAV (Yu et al., 2006; Connolly et al., 2007) and the point in the PSA history at which PSAV is calculated (Carter et al., 1992b; D'Amico et al., 2004).

PSAV may play a role in the prediction of life-threatening prostate cancer (Carter et al., 2006; D'Amico et al., 2004, 2005). A PSAV value greater than 0.35 ng/mL/year 10 to 15 years before diagnosis was associated with a fivefold increased risk for life-threatening prostate cancer more than 1 decade later (Carter et al., 2006); a PSAV value greater than 2 ng/mL/year during the year before a prostate cancer diagnosis was associated with prostate cancer–specific mortality after radical prostatectomy or radiation therapy (D'Amico et al., 2004, 2005; Sengupta et al., 2005). A systematic review of studies up to 2007 suggested that PSAV before treatment provides no additional information regarding prostate cancer outcome when compared with PSA alone (Vickers et al., 2009). However, several large recent studies have shown that PSA kinetics enhance predictive value for overall and high-risk disease beyond tPSA level alone (Loeb et al., 2012; Wallner et al., 2013).

Free Prostate-Specific Antigen.

Men with prostate cancer generally have a greater fraction of serum cPSA—and therefore a lower percentage of tPSA circulating in the free (unbound) form—than men without prostate cancer (Catalona et al., 1995, 1998, 2000a; Christensson et al., 1993; Gann et al., 2002; Hugosson et al., 2003a; Keetch et al., 1997; Leinonen et al., 1993; Lilja, 1993; Pannek et al., 1998; Raaijmakers et al., 2004a; Roehl et al., 2002; Stenman et al., 1994; Woodrum et al., 1998). This difference is thought to be caused by differential expression of PSA isoforms by transition zone (zone of origin of BPH) tissue compared with peripheral zone tissue (where most prostate cancers arise) (Chen et al., 1997; Mikolajczyk et al., 1997, 2000a, 2000b).

fPSA levels vary directly by age and prostate volume and vary indirectly with the tPSA level (Woodrum et al., 1998). In addition, because assays differ in their ability to determine both fPSA and tPSA, results may differ depending on the assay or combination of assays used (Woodrum et al., 1998). The percentage of fPSA (%fPSA) does not appear to be significantly altered by race (Catalona et al., 2000a) or 5α-reductase inhibitors (Keetch et al., 1997; Pannek et al., 1998).

%fPSA has been shown to significantly improve the ability to distinguish between individuals with and without prostate cancer, compared with tPSA alone (Christensson et al., 1993). The %fPSA cutoff that optimizes sensitivity and specificity for cancer detection depends on prostate size because overlap is greatest among men with enlarged prostates with or without concomitant prostate cancer (Catalona et al., 1995).

%fPSA appears to be most useful in distinguishing between those with and without prostate cancer at intermediate tPSA levels. In men with PSA levels of 4 to 10 ng/mL and palpably benign prostate glands, a %fPSA cutoff of 25% detected 95% of cancers while avoiding 20% of unnecessary biopsies (Catalona et al., 1998). The value of %fPSA to predict prostate cancer at levels below 4.0 ng/mL is unclear (Gann et al., 2002; Hugosson et al., 2003a; Raaijmakers et al., 2004a; Roehl et al., 2002).

%fPSA (at a cutoff of 25%) and PSAD (using a threshold of 0.078) have been shown to have comparable specificity (at a sensitivity of 95%), whereas %fPSA does not require volume measurement (Catalona et al., 2000b). Thus %fPSA or PSAD can be used to counsel men with PSA elevations in the range 4 to 10 ng/mL regarding their risk for cancer.

Complexed Prostate-Specific Antigen.

Because men with prostate cancer have a greater fraction of tPSA that is complexed to proteins than men without prostate cancer, measurement of cPSA has been studied as a marker for detection (Brawer, 2002; Brawer et al., 2000; Okegawa et al., 2000; Parsons et al., 2004). When tPSA levels were between 4 and 10 ng/mL, cPSA provided improved specificity compared with tPSA and similar specificity compared with the percentage of fPSA at a sensitivity of 95% (Brawer et al., 2000), findings that were subsequently confirmed (Okegawa et al., 2000). Similar results were reported in the PSA range of 2.6 to 4.0 ng/mL (Parsons et al., 2004). **Overall, at a high sensitivity, cPSA provides higher specificity than tPSA and comparable specificity to %fPSA in prostate cancer detection.** A potential advantage of cPSA is the requirement for one assay.

Prostate-Specific Antigens Isoforms.

PSA is secreted from the prostatic luminal epithelium in a precursor form (pPSA or proPSA) (see Chapter 149) (Canto et al., 2004; Catalona et al., 2003, 2004; Gretzer and Partin, 2003; Khan et al., 2003; Lilja, 2003; Lein et al., 2005; Makarov et al., 2008; Mikolajczyk et al., 2001, 2004; Peter et al., 2001). Active fPSA can be further cleaved to benign PSA (bPSA) or intact PSA (iPSA) that is inactive and not complexed. Assays have been developed to measure these different isoforms.

The relative concentration of these isoforms differs in the presence of prostatic disease. bPSA is found preferentially in nodular BPH tissue from the transition zone and can be considered a marker for BPH (Canto et al., 2004; Mikolajczyk et al., 2000b), whereas a larger relative proportion of proPSA has been associated with prostate cancer (Mikolajczyk et al., 1997, 2000a, 2001; Peter et al., 2001). Large studies have suggested that proPSA may improve the identification of prostate cancer among men with PSA levels of 2 to 4 ng/mL (Catalona et al., 2003, 2004), 4 to 10 ng/mL (Khan et al., 2003; Mikolajczyk et al., 2004), and 2 to 10 ng/mL (Catalona et al., 2003), whereas other studies have not shown incremental predictive value of specific subtypes beyond %fPSA (Lein et al., 2005).

Human Kallikrein 2.

Human kallikrein 2 *(hK2)* is a closely related serine protease in the PSA/kallikrein gene family that also has been evaluated for prostate cancer detection (Bangma et al., 2004; Becker et al., 2000, 2003; Haese et al., 2003;

Kwiatkowski et al., 1998; Partin et al., 1999; Steuber et al., 2005; Vickers et al., 2008). Expression of *hK2* is higher in more poorly differentiated cancer tissues than in normal and benign tissues (Tremblay et al., 1997). Although some studies have suggested that the ratio of *hK2* and fPSA might improve the ability of PSA to identify men with prostate cancer (Becker et al., 2000; Kwiatkowski et al., 1998; Partin et al., 1999; Vickers et al., 2008), other analyses have not (Bangma et al., 2004; Becker et al., 2003). *hK2* does appear to correlate directly with grade and cancer volume and could be useful in patient assessment after diagnosis (Haese et al., 2003; Steuber et al., 2005).

Multiplex Tests.

The discovery of these different PSA isoforms led to the development of combination tests. The Beckman Coulter Prostate Health Index (phi) is an FDA-approved test that combines tPSA, fPSA, and [−2] proPSA using a mathematical formula. In prospective multicenter trials, the use of phi demonstrated improved predictive accuracy for prostate cancer detection and high-grade disease compared with either tPSA or %fPSA (Catalona et al., 2011; Guazzoni et al., 2011). A similar test—the 4 kallikrein score (4K)—also has been developed, combining tPSA, fPSA, iPSA, and hK2 (Vickers et al., 2011). The 4K score also has been shown to predict the likelihood of clinically significant prostate cancer (Carlsson et al., 2013; Parekh et al., 2015).

Other Markers

Prostate cancer gene 3 *(PCA3)* is a noncoding prostate-specific messenger RNA (mRNA) overexpressed in prostate cancer tissue compared with benign tissue (see Chapter 149) (Bussemakers et al., 1999; Deras et al., 2008; Haese et al., 2008; Marks et al., 2007; Nakanishi et al., 2008; Sokoll et al., 2008; van Gils et al., 2008; Whitman et al., 2008). Urine assays have been developed to measure *PCA3* mRNA (Sokoll et al., 2008), which is associated with the likelihood of a positive initial or repeat prostate biopsy (Deras et al., 2008; Haese et al., 2008; Marks et al., 2007). There are conflicting results on the association between *PCA3* and prostate cancer aggressiveness (Nakanishi et al., 2008; van Gils et al., 2008; Whitman et al., 2008).

Another urinary marker is the *TMPRSS2:ERG* gene fusion (Salagierski and Schalken, 2012). The concept of gene fusions has a long history in other forms of malignancy (e.g., *BCR-ABL* in leukemia), and previous studies suggested that *TMPRSS2:ERG* gene fusions had increased specificity for prostate cancer. As with *PCA3*, however, there is conflicting data on the association of *TMPRSS2:ERG* with prostate cancer aggressiveness. Several new urinary markers have recently become commercially available, including the MiPS test combining PCA3 with TMPRSS2:ERG, SelectMDx which calculates a risk score based on a two-gene mRNA urine assay, and the ExoDx exosomal RNA (exoRNA)-based assay (McKiernan et al., 2016; Tomlins et al., 2016; Van Neste et al., 2016).

For patients with an initial negative prostate biopsy but with persistent suspicion for prostate cancer, molecular changes in the benign biopsy tissue may signify an increased or decreased risk for finding cancer in a subsequent biopsy. Confirm MDx (MDxHealth, Irvine, CA), a multiplex DNA methylation test performed on benign biopsy tissue, can select men with a low likelihood of having cancer on repeat prostate biopsy (negative predictive value >90%) (Partin et al., 2014). Such testing may reduce the need for unwarranted repeat biopsy sessions.

Overall, in the future, it is likely that panels of serum, urinary, and/or tissue biomarkers will be used in combination with standard measures of risk (age, family history, race) and imaging (MRI) to selectively identify men who should undergo further evaluation for the presence of prostate cancer (Etzioni et al., 2003).

Staging

General Concepts of Staging

The clinical staging of prostate cancer uses pretreatment parameters to predict the extent of disease, both for assessment of prognosis and to inform decisions regarding appropriate treatment. Available pretreatment modalities used to predict disease extent in men with prostate cancer include DRE (clinical T stage), PSA and its derivatives, prostate cancer features on needle biopsy, and radiologic imaging. Pelvic lymph node biopsy is rarely performed before definitive therapy.

Clinical Versus Pathologic Staging

Clinical staging is the assessment of disease extent using pretreatment parameters (DRE, PSA values, needle biopsy findings, and radiologic imaging), whereas pathologic stage is determined after prostate removal and involves histologic analysis of the prostate, seminal vesicles, and pelvic lymph nodes if lymphadenectomy is performed. Pathologic staging more accurately estimates disease burden and is more useful than clinical staging for outcome prediction (Pound et al., 1997). Biochemical recurrence-free survival and cancer-specific survival are both inversely related to the pathologic stage of disease (Roehl et al., 2004). The most important pathologic criteria that predict prognosis after radical prostatectomy are tumor grade, surgical margin status, extracapsular disease, seminal vesicle invasion, and pelvic lymph node involvement (Epstein, 1990, Epstein et al., 1993a, 1993b; Jewett, 1975; Partin et al., 1993a; Pound et al., 1997; Walsh and Jewett, 1980).

Classifications

The Whitmore and Jewett staging system is now of historical interest (Jewett, 1956; Whitmore, 1956). Today, clinical staging is based on the tumor, node, metastasis (TNM) classification system (Table 152.2). This system was first adopted in 1975 by the American Joint Committee on Cancer (AJCC) and since has undergone numerous modifications (American Joint Committee on Cancer, 2010; Schröder et al., 1992). In the most recent version, the TNM stage is combined with PSA level and grade group 1 to 5 (representing Gleason scores of

≤6, 3+4, 4+3, 8, and 9–10) to classify newly diagnosed cases into prognostic stage groupings (Buyyounouski et al., 2017).

TABLE 152.2

1997 and 1992 TNM Clinical Staging Systems for Prostate Cancer

1997	**1992**	**DESCRIPTION**
TX	TX	Primary tumor cannot be assessed
T0	T0	No evidence of primary tumor
T1	T1	Nonpalpable tumor—not evident by imaging
T1a	T1a	Tumor found in tissue removed at TUR; ≤5% is cancerous and histologic grade <7
T1b	T1b	Tumor found in tissue removed at TUR; >5% is cancerous or histologic grade >7
T1c	T1c	Tumor identified by prostate needle biopsy as a result of elevation in PSA
T2	T2	Palpable tumor confined to the prostate
T2a		Tumor involves one lobe or less
	T2a	Tumor involves less than one-half of one lobe by normal tissue on all sides
T2b		Tumor involves more than one lobe
	T2b	Tumor involves more than one-half of one lobe but not both lobes
None	T2c	Tumor involves more than one lobe
T3	T3	Palpable tumor beyond prostate
T3a	T3a	Unilateral extracapsular extension
T3b	T3b	Bilateral extracapsular extension
T3c	T3c	Tumor invades seminal vesicle(s)
T4	T4	Tumor is fixed or invades adjacent structures (not seminal vesicles)
T4a	T4a	Tumor invades bladder neck, external sphincter, and/or rectum
T4b	T4b	Tumor invades levator muscle and/or is fixed to pelvic wall
N(+)	N(+)	Involvement of regional lymph nodes
NX	NX	Regional lymph nodes cannot be assessed
N0	N0	No lymph node metastases
N1	N1	Metastases in single regional lymph node, ≤2 cm in dimension
N2	N2	Metastases in single (>2 but ≤5 cm) or multiple with none >5 cm
N3	N3	Metastases in regional lymph node >5 cm in dimension
M(+)	M(+)	Distant metastatic spread
MX	MX	Distant metastases cannot be assessed
M0	M0	No evidence of distant metastases
M1	M1	Distant metastases
M1a	M1a	Involvement of nonregional lymph nodes

M1b	M1b	Involvement of bones
M1c	M1c	Involvement of other distant sites

PSA, Prostate-specific antigen; *TNM,* tumor, node, metastasis; *TUR,* transurethral resection.

Prediction of Tumor Extent

Prostate-Specific Antigen

Despite controversy over its correlation with prostate cancer volume (Stamey et al., 2004), PSA levels are associated directly with pathologic stage and tumor extent (Stamey et al., 1987, 1989). PSA values cannot be used alone to accurately predict disease extent for an individual patient because of significant overlap in PSA levels between stages, the variable contribution from BPH to PSA, and the fact that—on average—poorly differentiated tumors produce less PSA per gram of tumor (Partin et al., 1990). Despite these confounding factors, pathologically organ-confined disease is found in 80% of men with a PSA less than 4.0 ng/mL, 66% of those with PSA levels between 4.0 and 10.0 ng/mL, and fewer than 50% of men with PSA levels greater than 10.0 ng/mL (Catalona et al., 1997; Rietbergen et al., 1999). Also, 20% of men with PSA levels greater than 20 ng/mL and 75% of those with PSA levels greater than 50 ng/mL are found to have pelvic lymph node involvement.

In addition to the tPSA level, fPSA, hK2, proPSA, PSAD, PSAV, and the newer PSA-based marker tests (see earlier discussion) have been evaluated as predictors of prostate cancer grade and extent (Cantiello et al., 2015; Carter et al., 1997b, 2006, 2007; D'Amico et al., 2004, 2005; Kundu et al., 2007; Loeb et al., 2008d; Southwick et al., 1999). Although prostatic acid phosphatase has been associated with pathologic stage and progression after radical prostatectomy (Moul et al., 1998; Han et al., 2001), the closer relationship between PSA levels and disease extent has virtually eliminated the clinical use of this parameter (Heller, 1987).

Digital Rectal Examination

DRE is used to determine whether a lesion is palpable and is associated with local disease extent (clinical T stage). Also, an abnormal DRE was associated with an increased risk for detecting high-grade (Gleason 8 to 10) prostate cancer in a screened population (Gosselaar et al., 2008).

However, because of its poor sensitivity and lack of reproducibility, DRE can both overestimate and underestimate the extent of disease (Byar and Mostofi, 1972; Turner and Belt, 1957; Walsh and Jewett, 1980). In one series of 565 men with presumed organ-confined disease based on DRE, the sensitivity and specificity were 52% and 81%, respectively, for prediction of organ-confined disease (Partin et al., 1993b). Nevertheless, DRE can be used in combination with other parameters to help predict tumor extent.

Prostate Needle Biopsy

Histologic grade is the most important information obtained from prostate needle biopsy, and the Gleason grading system is the most commonly used (Gleason, 1966). At low-power magnification, the sum of a grade (1 to 5) assigned to the predominant pattern (occupying the largest area of the specimen) and the second most common pattern yield a score ranging from 2 to 10.

Contemporary studies have shown that tertiary Gleason patterns may affect prognosis (Patel et al., 2007), leading a 2005 consensus conference to recommend modification of the Gleason grading system (see Chapter 151). Accordingly, a biopsy Gleason score of 3+4 or 4+3 with a tertiary pattern 5 would be considered Gleason 3+5 or 4+5, respectively (Epstein et al., 2005).

Over the years, the Gleason grading system has undergone several changes. Currently, Gleason total scores 2 to 5 are no longer assigned, and in practice the lowest total score is now assigned a 6, although the scale continues to range from 2 to 10. This results in confusion for patients and may present a barrier to active surveillance for patients with Gleason 6 disease (Loeb et al., 2016). To address these issues, a new 5-grade group system has been developed (Pierorazio et al., 2013):

Grade Group 1 (Gleason score ≤6)
Grade Group 2 (Gleason score 3+4=7)
Grade Group 3 (Gleason score 4+3=7)
Grade Group 4 (Gleason score 4+4=8)
Grade Group 5 (Gleason scores 9 and 10)

The new system simplifies the grading of prostate cancer, appropriately classifies the lowest risk as Grade Group 1 (rather than Gleason score 6), and accurately predicts prognosis (Pierorazio et al., 2013).

Although a higher Gleason score/grade group is associated with a poorer prognosis, it is not used alone for risk prediction (Epstein et al., 1993a, 1993b; Partin et al., 1993a; Stein et al., 1991; Zincke et al., 1994). Other biopsy findings provide information regarding the extent of disease, including the number of positive cores, percentage of positive cores, and presence of perineural invasion. These features are associated with radical prostatectomy findings and have been used to guide the selection of candidates for active surveillance programs (Bismar et al., 2003; Carter et al., 2002; de la Taille et al., 1999a; Egan and Bostwick, 1997; O'Malley et al., 2002).

Findings of seminal vesicle invasion or involvement of the periprostatic fat on prostate needle biopsy are associated with poorer prognosis (Stone et al., 1998). Although some authors have recommended biopsy of the seminal vesicles and/or prostatic capsule to improve staging (Ravery et al., 1994; Stone et al., 1995, 1998; Terris et al., 1993; Vallancien et al., 1994), others suggest biopsy of these structures only when there is a large palpable tumor located at the base of the prostate (Guillonneau et al., 1997; Terris et al., 1997).

Combined Use of Pretreatment Parameters

Nomograms and algorithms have been developed to integrate multiple clinical parameters for improved staging. Considering the primary T stage based on DRE findings, serum PSA level, and Gleason score/grade group, these algorithms and nomograms have been shown to more accurately predict both cancer extent and long-term outcomes after treatment compared with any single parameter (Humphrey et al., 1991; Kleer and Oesterling, 1993; Kattan et al., 1998; Han et al., 2003; Kleer et al., 1993; Makarov et al., 2007; Partin et al., 1993b, 1997, 2001; Stephenson et al., 2006; Tosoian et al., 2017).

Several classification schemes have been proposed that correlate with clinical outcomes. D'Amico et al. (1998, 2001) demonstrated that stratification into low-risk (clinical stage T1 to 2a, PSA ≤10 ng/mL, and Gleason score ≤6), intermediate-risk (stage T2b or PSA >10 but <20 ng/mL or Gleason score 7), and high-risk (stage T2c, or PSA >20 ng/mL or Gleason score 8 to 10) disease was significantly associated with freedom from disease at 10 years after radical prostatectomy; 83% for low-risk, 46% for intermediate-risk, and 29% for high-risk disease. Other validated classification schemes have been developed since, including the Cancer of the Prostate Risk Assessment (CAPRA) score (Cooperberg et al., 2005, 2006; May et al., 2007). Pretreatment risk stratification using multiple parameters is useful for patient counseling.

Imaging

Numerous imaging modalities have been evaluated for staging prostate cancer. In the United States, radionuclide bone scan (bone scintigraphy) is the most commonly employed modality for the detection of skeletal metastases (Terris et al., 1991). Bone survey films (skeletal radiography) have lower sensitivity for the identification of distant spread and are typically used only to confirm a positive bone scan in men at low risk for bone metastases. Because bone metastases at diagnosis are uncommon in asymptomatic men in the PSA era, the routine use of bone scans in this population may lead to false-positive results, and unnecessary anxiety and cost (Chybowski et al., 1991). Accordingly, recent guidelines recommend the use of bone scans for patients with clinical stage T1 and a PSA level greater than 20 ng/mL, clinical stage T2 and a PSA level greater than 10 ng/mL, a Gleason score of 8 to 10 (Grade group 4-5), clinical stage T3 or T4, or clinical symptoms (National Comprehensive Cancer Network, 2017). The Choosing Wisely Campaign emphasizes that routine bone scans are not necessary for men with low-risk prostate cancer (American Urological Association, 2013b).

Similarly, cross-sectional imaging to evaluate for lymphadenopathy is recommended for high-risk patients, such as those with clinical stage T3 or greater disease or greater than 10% nomogram probability of lymph node metastases (National Comprehensive Cancer Network, 2017). Given the rarity of lymph node involvement in contemporary screened populations, it appears that imaging is being overused (Abraham et al., 2007; Cooperberg et al., 2002; Kindrick et al., 1998).

Although magnetic resonance imaging (MRI) has been evaluated for staging prostate cancer for many years (Kurhanewicz et al., 2000; Yu et al., 1999), the technology has recently improved dramatically. In particular, the addition of functional sequences such as diffusion-weighted MRI and dynamic contrast-enhanced MRI in conjunction with the conventional T2-weighted MRI has improved the ability of MRI to characterize the locoregional extent of disease. It is currently used at some institutions for pretreatment planning before definitive local therapy or to assess candidacy for active surveillance (Somford et al., 2013; Vargas et al., 2012). In addition, MRI images may be fused with transrectal ultrasound to enable targeted prostate biopsy (Siddiqui et al., 2015; Sonn et al., 2014). A consensus statement from the AUA and the Society of Abdominal Radiology recommended that when high-quality MRI is available, it should be strongly considered for men with a prior negative biopsy under consideration for repeat biopsy (Rosenkrantz et al., 2016). Patients with a suspicious lesion on MRI warrant repeat biopsy with image-guided targeting.

Specialized techniques such as high-resolution MRI used in tandem with the intravenous administration of lymphotropic superparamagnetic nanoparticles may allow the detection of small and otherwise undetectable lymph node metastases in patients with prostate cancer (Harisinghani et al., 2003). These techniques, however, require further clinical evaluation before widespread use.

Advances in ultrasound imaging are also being studied for improving prostate cancer detection (Purohit et al., 2003). Color ultrasonography with power Doppler to evaluate the blood flow within prostate vessels and three-dimensional Doppler using contrast agents could improve the visualization of more subtle tissue alterations caused by cancer. Another new ultrasound-based technique is HistoScanning (BK Medical, Peabody, MA), a computer-aided process to help characterize potentially suspicious tissue (Simmons et al., 2012). Additional large-scale studies of these techniques are necessary before widespread use can be recommended.

Finally, monoclonal antibody radioimmunoscintigraphy (radiolabeled monoclonal antibody scan) has been used for identification of microscopic cancer deposits in regional and distant sites. The ProstaScint scan (Cytogen, Princeton, NJ) uses this technology but has had limited accuracy in the detection of lymph node metastases because the antibody targets an intracellular epitope that is exposed only in dying or dead cells (Chang et al., 1999; Troyer et al., 1997). Future generations of this technology circumventing this limitation are under development.

Molecular Staging

Molecular staging has focused on the detection of circulating prostate cancer cells either directly through centrifugation/immunostaining methods or indirectly by identifying the genetic material for prostate-specific biomarkers (e.g., PSA, prostate-specific membrane antigen) from circulating prostate cells (Moreno et al., 1992; Ts'o et al., 1997). Although these polymerase chain reaction (PCR)-based assays have been associated with pathologic stage, sensitivity for detecting circulating cancer cells is variable across studies (Cama et al., 1995; de la Taille et al., 1999b; Israeli et al., 1995). With FDA approval of the semiautomated CellSearch system (Veridex, Janssen Diagnostics, Raritan, NJ) for monitoring metastatic breast and prostate cancer, considerable investigation is underway to determine whether circulating tumor cells have a role in the staging of early disease (Davis et al., 2008; Helo et al., 2009).

Several new tissue-based tests have been introduced that may improve prostate cancer risk stratification. The Prolaris test (Myriad Genetics, Salt Lake City, UT) measures a panel of cell cycle progression genes involved in the process of cancer proliferation (Cooperberg et al., 2013). The Oncotype DX Prostate Cancer Test (Genomic Health, Redwood City, CA) is a quantitative RT-PCR assay for 17 genes involved from five different pathways involved in prostate carcinogenesis (Knezevic et al., 2013). Finally, the Decipher test measures the expression levels of 22 RNA biomarkers involved in multiple biologic pathways (Klein et al., 2016). Preliminary studies of these tests suggest a potential ability to further refine classification schemes beyond the standard risk groups (Klein et al., 2014); however, further prospective validation studies are necessary to demonstrate whether these tests are cost-effective.

Pelvic Lymphadenectomy

The presence of lymph node metastasis in men diagnosed with clinically localized prostate cancer portends a poorer prognosis. Identification of patients harboring nodal metastases could have important implications for treatment selection. Although the prevalence of pelvic lymph node metastases correlates directly with T stage, serum PSA level, and biopsy grade, pelvic lymphadenectomy remains the most accurate way to detect occult nodal involvement (Parker et al., 1999).

PSA screening has resulted in a decline in the rates of metastases from 20% to 40% in the 1970s and 1980s to less than 4% today (National Cancer Institute, 2013; Parker et al., 1999; Partin et al., 1997). Currently, lymphadenectomy often is omitted before curative treatment (e.g., radical prostatectomy, radiation therapy) (Bishoff et al., 1995; Kawakami et al., 2006). Laparoscopic pelvic lymphadenectomy before treatment is typically reserved for patients with a Gleason score greater than 8, extraprostatic extension on DRE, PSA value greater than 20 ng/mL, or suspicion of enlarged lymph nodes on radiologic evaluation, and it is rarely performed in the contemporary PSA era.

Given the individual variation in prostatic lymphatic drainage patterns (Mattei et al., 2008), some investigators favor an extended pelvic lymphadenectomy in lieu of a limited dissection (Bader et al., 2002; Burkhard et al., 2006).

Considering the greater complication rates with a more extended pelvic lymph node dissection, risks may outweigh benefits for most men diagnosed with low-risk cancer today (Klein et al., 2008). Information regarding the therapeutic value of these strategies is confounded by stage migration and is difficult to evaluate without prospective trials.

Key Points: Diagnosis and Staging of Prostate Cancer

- Although the value of PSA screening remains controversial, men who present for periodic health examinations should be made aware of the availability of the PSA test so they can make an informed decision about screening.
- The combination PSA level, DRE, and other clinical factors (e.g., age, race, family history) can be used in combination to predict the risk that prostate cancer is present. The presence of prostate disease (prostate cancer, BPH, and prostatitis) is the most important factor affecting serum levels of PSA.
- PSA testing increases detection rates of prostate cancer and leads to the detection of prostate cancers that are more likely to be organ-confined when compared with detection without the use of PSA.
- The future risk for prostate cancer detection and the chance of finding cancer on a prostate biopsy increase incrementally with serum PSA level.
- Biochemical recurrence-free survival and cancer-specific survival are both inversely related to the pathologic stage of disease.
- Pathologic criteria that predict prognosis after radical prostatectomy are tumor grade, surgical margin status, presence of extracapsular disease, seminal vesicle invasion, and pelvic lymph node involvement.
- The Gleason grading system is the most commonly used classification scheme for the histologic grading of prostate cancer.

Active Management Strategies for Localized Prostate Cancer

Samir S. Taneja MD, Marc A. Bjurlin DO, MSc

The active management of clinically localized prostate cancer has evolved immensely over the past two decades because of an expanding knowledge of the disease and the inherent risks it presents to the individual patient. With the advent of prostate-specific antigen (PSA) testing and community-based screening in the early 1990s, a uniform approach to the disease emerged with radical treatment for most men, regardless of disease risk. The apparent benefit of such an approach was supported by an observed serially declining rate of prostate cancer mortality among American men over the ensuing decades (Schroder et al., 2014; Tsodikov et al., 2018).

As experience with treatment increased, a number of observations drew into question the idea of aggressively treating all men with prostate cancer. Studies of observation among men with low-risk prostate cancer demonstrated low rates of metastatic progression and prostate cancer death. Randomized studies of treatment versus observation failed to demonstrate a reduction in prostate cancer mortality, largely because of a high rate of death from other causes during the early follow-up period (Wilt et al., 2012). Large randomized studies of PSA screening failed to demonstrate robust declines in prostate cancer mortality for all patients, despite prolonged follow-up (Andriole et al., 2009, 2012). Collectively, these observations drew harsh criticism for the practice of aggressive detection and treatment of prostate cancer.

Although it is clear that aggressive prostate cancer treatment does not benefit all men with prostate cancer, a number of men diagnosed with early stage disease remain at significant risk of prostate cancer mortality within their lifetime. As such, the contemporary approach to localized prostate cancer is highly individualized with careful assessment of longevity, disease aggressiveness and extent, and patient goals. **Current active management of prostate cancer requires an individualized assessment of the risk of prostate**

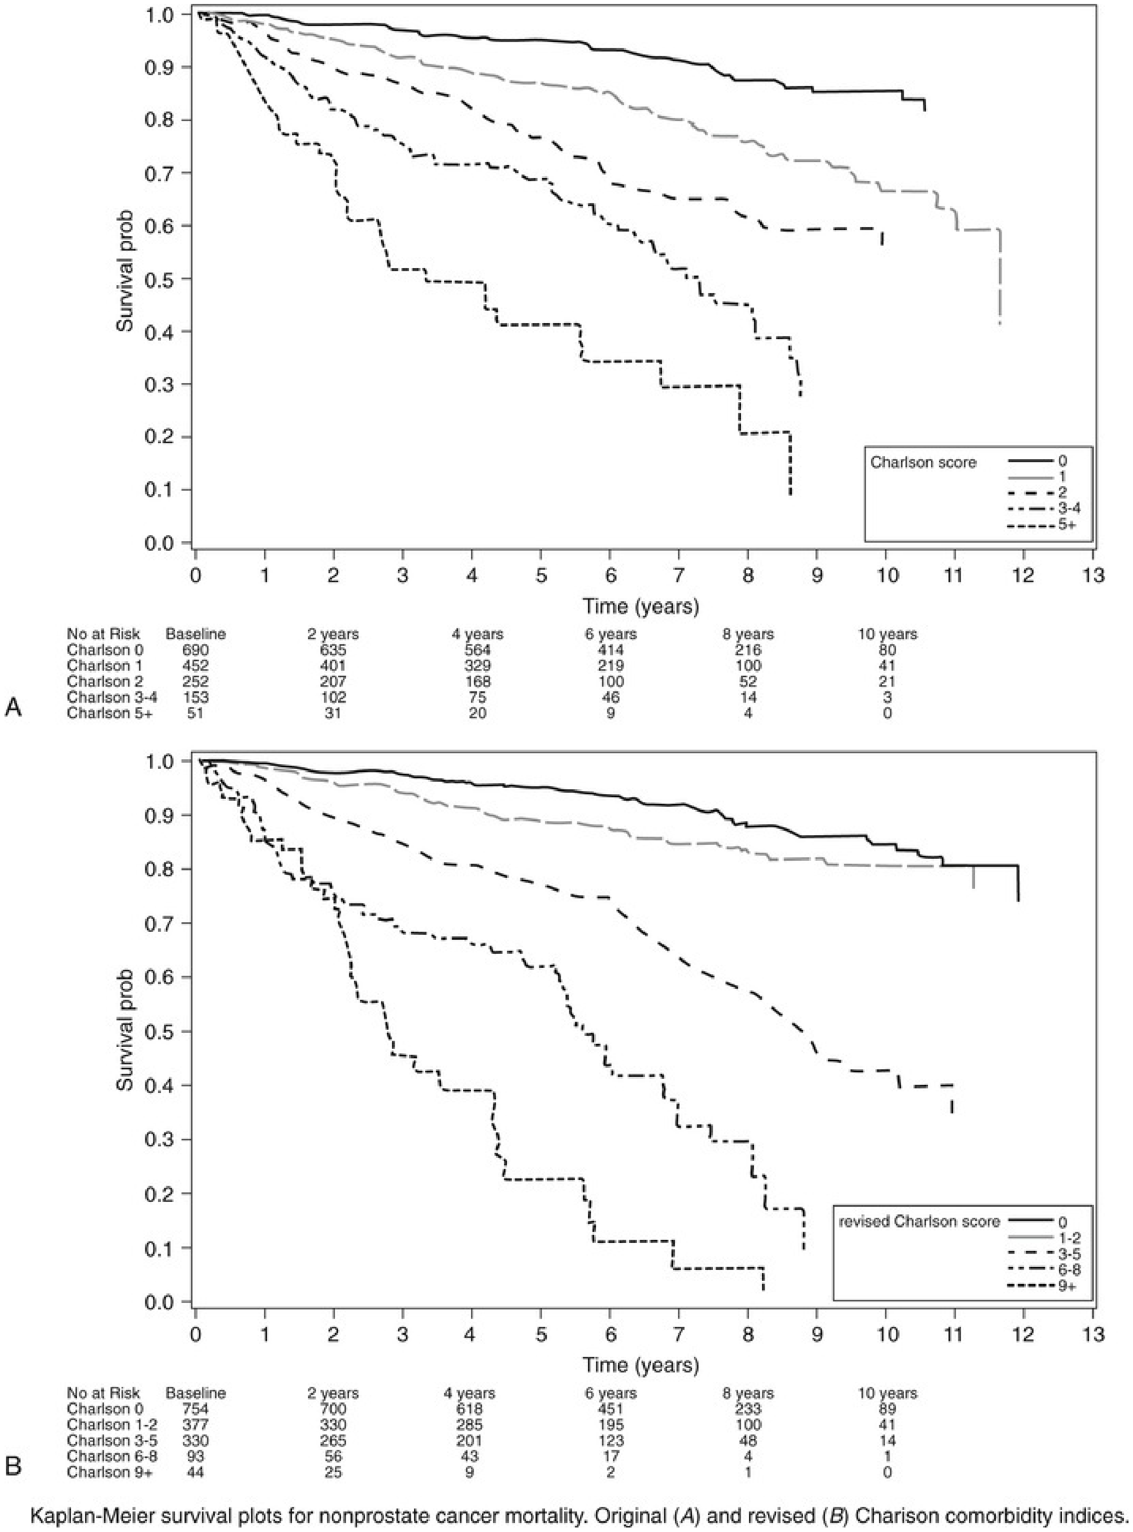
cancer mortality relative to other competing risks for death over time. For those men who are thought more likely to die of competing risks than prostate cancer, observation is a reasonable choice. For those men with good longevity, in whom it is not clear that treatment will be likely to improve longevity, active surveillance has emerged as a rational means of deferring therapy until more clear evidence emerges for need of therapy. Among those men deemed to be in need of therapy, a number of treatment options exist, including radical prostatectomy, externally delivered radiation therapy, interstitial radiation, and thermal ablative therapies for whole or partial gland ablation. **Selection of the appropriate therapeutic modality requires careful counseling regarding the risks and benefits, recognition of host factors influencing the risks and benefits of therapy, and patient preference.** The active management of localized prostate cancer requires careful evaluation of the host, cancer risk assessment, and patient counseling to include comparative data and detailed discussion of individual treatment options.

Host Evaluation

Longevity Assessment and Competing Risks for Mortality

The value of prostate cancer treatment has, in recent years, been considered in the context of life expectancy and risk of death from other causes. Such considerations are rooted in the observation of large trials assessing the efficacy of prostate cancer therapy in which high rates of death from competing causes dilute the survival benefits of treatment (Daskivich et al., 2015; Wilt et al., 2017). The National Comprehensive Cancer Network (NCCN) stresses that "Life expectancy estimation is critical to informed decision-making in prostate cancer early detection and treatment." Several randomized clinical trials have suggested that the risk of death from other causes exceeds the risk of death from prostate cancer (Bill-Axelson et al., 2014; Wilt et al., 2012). From data collected in the Prostate Cancer Outcomes Study, a US prospective cohort of men with localized prostate cancer, the risk of death from other causes can be modeled as a function of comorbidity and age (Daskivich et al., 2011b). The 10-year risk of death from prostate cancer ranged from 3% to 18% depending on the risk category, whereas men with any comorbidity had a 10-year mortality rate from other causes of 33% or higher (Daskivich et al., 2011b). Although conventional wisdom has resulted in the general dogma that men should have a perceived good likelihood of 10-year longevity to benefit from therapy, in practice broad application of this simple rule has resulted in lower rates of treatment among young men, and, perhaps, overtreatment in younger men. **In best practice, decisions regarding the benefit of treatment should be rooted in an individualized assessment that includes age, comorbidities, and risk of cancer mortality.**

The NCCN has recommended use of the Social Security Administration Tables or the World Health Organization's Life Tables in estimating longevity, but other tools have developed more specifically for assessment of men with prostate cancer (Daskivich et al., 2011a, 2015). In these models, the relationship of age and comorbidity becomes a critical component in applying longevity estimates at the time of diagnosis. Longevity assessment in the prostate cancer patient is an indirect measure of comorbidity and competing risks for mortality. Such risks influence not only the decision whether the patient should undergo therapy but also the type of treatment to be considered. In the case of significant cardiac, pulmonary, or hematologic comorbidity, reasonable longevity and estimated benefit for treatment may be preserved, but surgery, as an example, may be contraindicated because of anesthesia or bleeding risks. The most widely used scale of comorbidity is the Charlson Co-morbidity Index (CCI). The CCI was designed to weigh comorbidities in prediction of 1-year mortality among inpatients (Charlson et al., 1987) but ultimately has been identified as a significant prognostic indicator in the treatment of many types of cancer (Asano et al., 2017; Mayr et al., 2014; Simon et al., 2012). In 2011 Daskivich et al. (2011a) created a prostate cancer–specific CCI (PCCI) weighing comorbidities to predict 10-year risk of mortality among prostate cancer patients (Fig. 153.1). When adjustments were made for age when applying the PCCI to men with prostate cancer in the Veterans Affairs Medical Center (VAMC), segregated PCCI score at 0, 1-2, 3-4, 5-6, 7-9, and 10, the 10-year cumulative incidence of other cause mortality was 10%, 19%, 35%, 60%, 79%, and 99%, respectively (Daskivich et al., 2015).



No at Risk	Baseline	2 years	4 years	6 years	8 years	10 years
Charlson 0	690	635	564	414	216	80
Charlson 1	452	401	329	219	100	41
Charlson 2	252	207	168	100	52	21
Charlson 3-4	153	102	75	46	14	3
Charlson 5+	51	31	20	9	4	0

No at Risk	Baseline	2 years	4 years	6 years	8 years	10 years
Charlson 0	754	700	618	451	233	89
Charlson 1-2	377	330	285	195	100	41
Charlson 3-5	330	265	201	123	48	14
Charlson 6-8	93	56	43	17	4	1
Charlson 9+	44	25	9	2	1	0

Kaplan-Meier survival plots for nonprostate cancer mortality. Original (*A*) and revised (*B*) Charlson comorbidity indices.

FIG. 153.1 Risks of other cause mortality associated with comorbidities in the original Charlson comorbidity index (A) and re-weighted comorbidity index identifying highest risk for other cause mortality (B) among men with prostate cancer. (From Daskivich TJ, Chamie K, Kwan L, et al.: Improved

prediction of long-term, other cause mortality in men with prostate cancer. *J Urol* 186(5):1868–1873, 2011.)

The perception of longevity in clinical practice is often based solely upon age rather than comorbidity. Daskivich et al. have previously demonstrated that among men with low-risk prostate cancer diagnosed in the VAMC, treatment rates were higher for men with CCI of at least 3 than those with age more than 75 years (54% vs. 16%), despite a much higher likelihood of other cause mortality within 10 years (70% vs. 24%) (Daskivich et al., 2011a). In addition, among men in the SEER-Medicare database, aggressive treatment for men with less than 10 years' life expectancy, based upon CCI, was dependent upon age, with 68% to 69% of men aged less than 75 receiving aggressive therapy compared with only 57% and 24% of those aged 75 to 79, or at least 80 (Daskivich et al., 2014). Similarly, Bratt et al. (2015) demonstrated that among men with high-risk prostate cancer in the National Prostate Cancer Register of Sweden, 50% of men younger than 70 years received radical treatment, as compared with only 10% of men aged 70 to 80, despite a 52% likelihood of 10-year longevity. **Improvements in appropriate candidate selection for treatment, and secondarily survival benefit, can be achieved through age-adjusted assessment of longevity on the basis of validated comorbidity indices and life tables.**

Longevity assessment must be contemplated within the context of cancer aggressiveness. Men with aggressive malignancies may benefit from diagnosis and treatment regardless of a shortened longevity, particularly if diagnosed at an advanced stage. In men with high-risk, poorly differentiated prostate cancer, within the SEER-Medicare dataset, when cancer-specific survival is compared, aggressive treatment resulted in mortality improvements of 11.3%, 7.9%, 8.6%, and 2.8% at 10 years' follow-up for men with Charlson scores of 0, 1, 2, and 3+, respectively; numbers needed to treat to prevent 1 cancer death at 10 years were 9, 13, 12, and 36 men (Daskivich et al., 2016). Lead time from diagnosis to symptoms and eventual cancer-related mortality are heavily influenced by Gleason score and tumor stage. This suggests that the relevance of expected longevity in treatment decision making must be framed within a temporal estimate of cancer progression and mortality risk. **Men with a high risk of metastatic progression or mortality within 10 years of diagnosis should be considered for aggressive therapy despite the presence of one or more competing risks for mortality within the same time period.**

Baseline Urinary, Sexual, and Bowel Function

Bladder Function

In consideration of the necessity for treatment and the appropriate type of treatment, the patient's baseline urinary, bowel, and sexual function are critical considerations because they influence the magnitude of benefit and risk to the patient with regard to quality of life. Patients with preexisting conditions may be at increased risk for either more intense morbidity or more protracted morbidity that may ultimately affect prostate cancer treatment choice. Careful assessment of baseline function using validated instruments to measure urinary and sexual function is necessary in formulating an individualized, balanced discussion of the risks and benefits of treatment in the shared decision-making process.

Baseline urinary function can be measured by a number of validated methods including, most commonly, the International Prostate Symptom Score (IPSS) and the UCLA Prostate Cancer Index (Barry et al., 1992; Litwin et al., 1998). In addition to an IPSS, a more detailed urinary history with analysis of the individual questions in the instrument is useful to delineate the nature of the symptoms. In men with obstructive symptoms resulting from benign prostatic hyperplasia (BPH), extirpative surgery may offer the added benefit of improvement in symptoms, although the patient may be at increased risk of retention if brachytherapy or external radiation is employed. In 2004 Lepor et al. demonstrated a 40% improvement in baseline urinary symptoms after radical prostatectomy among men with moderate to severe urinary symptoms (Lepor and Kaci, 2004), which was subsequently shown to persist through long-term follow-up without clinically significant age-related progression of lower urinary tract symptoms typically observed in the general population (Prabhu et al., 2014; Slova and Lepor, 2007; Xu et al., 2018). Others have subsequently made similar observations (Gordon et al., 2014, 2016), although Choi et al. (2011) and Kim et al. (2013) have observed that men with severe baseline urinary symptoms suffer more urinary bother in the early postoperative period. Among men with large prostates and moderate symptoms, these data should be considered given the long-term risk of progressive urinary symptoms and eventual retention. In these patients, prostatectomy may have long-term benefits in this regard.

The effect of radiotherapy on baseline urinary symptoms has been less well reported but is typically characterized as transient worsening, followed by normalization, followed by improvement in symptoms as the prostate regresses.

Men with severe irritative symptoms at time of diagnosis are at highest risk of worsening of symptoms after radiation because many may have underlying bladder overactivity and potential compliance abnormalities. Although the severity of urinary toxicity may vary with different forms of radiation therapy, in general the relative risk of short-term toxicity for men with severe baseline symptoms is comparable. Men with large prostates and obstructive symptoms are likely to be at increased risk of retention after brachytherapy, but this is not clearly shown after externally delivered forms of radiation therapy.

Prostate size is often an important consideration when selecting a therapy for early-stage disease. The American Brachytherapy Society guidelines suggest that prostate glands that are greater than 60 cm (Wilt et al., 2012) are technically more difficult to implant because of increased frequency of pubic arch interference and the large number of seeds required (Davis et al., 2012). Using cytoreductive androgen deprivation therapy (ADT) can reduce prostate volumes by approximately 25% to 40% and may be helpful to optimize gland size before brachytherapy. In patients with prostate volumes in excess of 80 g, neoadjuvant ADT may be required for cytoreduction before radiotherapy with the goal of reducing the volume of rectum or bladder exposed to the high doses of irradiation. For patients with early-stage disease with unusually large prostates, surgery may be the preferred intervention, which would avoid the need for several months of ADT and its associated side effects.

Among men with chronic retention requiring indwelling catheter or intermittent catheterization, surgery should be considered if the retention is deemed obstructive. If retention is due to bladder atony, surgery may still be performed, although bladder compliance, as assessed by urodynamic evaluation, will predict the likelihood of recovery of incontinence. With radiation therapy, removal of catheter, with conversion to intermittent catheterization, is advisable to allow cycling of the bladder wall and secondary prevention of bladder wall fibrosis resulting from radiation injury.

Transurethral resection of the prostate (TURP) before external radiation, rather than after, may be advisable for men in, or at risk of, retention. In these men, if post-treatment transurethral resection is performed, there may be a higher associated risk of incontinence (Polland et al., 2017), particularly after brachytherapy with up to 18% of men incontinent after TURP (Hu and Wallner, 1998; Kollmeier et al., 2005). Historically, TURP before brachytherapy was associated with a higher risk of post-implant incontinence (Blasko et al., 1991), although more contemporary experience challenged this notion (Stone et al., 2000; Wallner et al., 1997). More recently, a limited TUR approach, with resection of obstructing median lobe/bladder neck and minimal resection of the lateral lobes and apex, has been described to be safe before brachytherapy (Brousil et al., 2015).

For men who have had a previous aggressive TURP for outlet obstruction, the risk of urinary toxicity may be higher in those that undergo radiotherapy (Devisetty et al., 2010; Sandhu et al., 2000), but the rates of long-term severe urinary symptoms may lower. Delay of radiation for 6 to 8 weeks after TURP may reduce the risk of incontinence and bladder neck contracture (Mansfield and Stephenson, 1996). Patients with a history of a TURP, transurethral microwave, or laser procedures may have large defects that pose a dosimetric challenge for brachytherapy given the desire to place radiation dose predominantly within the gland periphery, avoiding the urethra and bladder neck. Similarly, if contemplating ablative cryosurgery, placement of needles is challenging in the setting of a large TURP defect, because of the risk of intraurethral needle placement. Small glands (<30 cm [Wilt et al., 2012]) with large TURP defects pose a particular challenge and may be better managed with alternative strategies.

Other forms of lower urinary tract dysfunction, because of neurogenic disease, should be carefully evaluated before prostate cancer therapy. In men with Parkinson disease, a careful urologic history should be undertaken to assess for any evidence of bladder dysfunction. Urodynamic evaluation before surgery or radiation may be useful in providing quantitative metrics by which to judge the likelihood of post-treatment incontinence and/or worsening of urinary symptoms. Men with severe compliance abnormalities may be better served by surgical therapy given the risk of progressive bladder fibrosis after radiation.

Sexual Function

Recovery of erectile function after therapeutic intervention is dependent upon several factors related to the quality and success of the treatment but also relates to several host attributes, including baseline sexual function, use of oral PDE5 inhibitors, frequency of sexual activity, and risk factors for sexual dysfunction, including diabetes, atherosclerotic disease, and hypercholesterolemia (Le et al., 2010). In a study of 966 men undergoing radical prostatectomy at a tertiary cancer center, age and preoperative erectile function were predictive of erectile function recovery after bilateral nerve preservation at 2 years postoperative (Krishnan et al., 2014). The same group has demonstrated that men with poor baseline erectile function are more likely to undergo non–nerve-sparing procedures, independent of the severity of their cancer (Stember et al., 2013), suggesting that baseline function influences the treatment plan. Increasing age has been associated with lower likelihood of potency recovery after surgery (Woo et al., 2014) and has similarly been shown to predict higher likelihood of sexual functional decline after radiation therapy (Litwin et al., 1999). Several groups have demonstrated a greater likelihood of postoperative sexual bother after prostatectomy, independent of sexual functional recovery, among men with more frequency of sexual activity preoperatively (Kimura et al., 2013; Steinsvik et al., 2012).

Bowel Function and Other Conditions Affecting Treatment Choice

In general, comparative data have suggested that men undergoing radiotherapy are at increased risk of bowel dysfunction after treatment than those undergoing surgery (Barocas et al., 2017; Resnick et al., 2013; Tyson et al., 2018). Although all men are generally at risk, a careful gastroenterologic history is essential for minimizing the risk among candidates considering radiation. Men with preexisting fecal frequency/urgency, irritable bowel, tenesmus, or extensive previous rectal surgery should be cautioned regarding an exacerbation of symptoms with treatment. For these men, a gastroenterologic evaluation before therapy is warranted. There has been a suggestion that patients with inflammatory bowel disease (e.g., Crohn disease, ulcerative colitis) have more severe acute and late toxicity with pelvic radiotherapy. Similarly, men with known neurogenic bladder dysfunction should be counseled regarding the risk of functional deterioration or incontinence after treatment. Similarly, men with preexisting bowel dysfunction resulting from neurogenic or inflammatory disease may be at risk of worsened bowel function upon administration of external radiation.

Previous radical pelvic irradiation is a specific contraindication to radiotherapy for prostate cancer and may influence the complexity of radical prostatectomy. A careful history regarding the dose and field of radiation will allow treatment planning and assessment of relative risk. Previous pelvic surgery, particularly those operations that potentially trap bowel within the pelvic field, may also be considered as risk factors for radiation enteritis. Similarly, the presence of substantial or susceptible bowel within the radiotherapy field, for example from a hernia, also is a relative contradiction for radiation treatment. Furthermore, some patients may not be optimal candidates for radiotherapy resulting from propensity for impaired tissue healing, such as those with poorly controlled diabetes. For similar reasons, chronic steroid therapy may be a relative contraindication to surgery given the risk of delayed healing.

Patient Preference and Biases

Patient preferences and values play an increasing role in medical decision making. In the specific setting of prostate cancer, largely because of the absence of compelling data supporting one treatment over another in individual cases, patient preference and views regarding treatment-related side effects play a major role in treatment choice. **Men often come to patient consultation with preconceived perceptions regarding prostate cancer treatment based upon the experiences and advice of family and friends, Internet research, and representations of treatment in the lay media.** In a recent survey of men diagnosed with prostate cancer before treatment, 59% of men indicated they only considered surgery as a treatment option (Zeliadt et al., 2010). Men choosing surgery are typically more concerned with cancer mortality, and those choosing nonsurgical options tend to be more concerned with quality of life. In addition, pretreatment urinary symptoms may influence treatment decision: men are more likely to elect surgery if confronted with obstructive urinary symptoms (Mazur and Merz, 1996).

Shared decision making involves a collaborative process in which patients and clinicians make decisions together. Given the controversy surrounding the relative benefit of prostate cancer screening and treatment, shared decision making, with regard to PSA testing and prostate cancer treatment, has been strongly advocated by a number of governing bodies. This shared decision-making model has been adopted into guidelines on localized prostate cancer management supported by the AUA, ASTRO, and the SUO (Sanda et al., 2018a). More recently, consensus has been achieved regarding strategies for implementation of shared decision making in clinical practice (Makarov et al., 2016).

In a recent multicenter, prospective, observational study of 454 men undergoing prostate cancer counseling and treatment, regardless of whether men expressed an initial desire to be actively or passively involved in decision making, after treatment, men who perceived their involvement in decision making as active were more well informed with regard to the disease and expressed less decisional regret in follow-up after treatment (van Stam et al., 2018).

Several interventions that include written material, in-person counseling, and web-based tools have been investigated. Although a meta-analysis of 14 randomized clinical trials investigating shared decision-making aids revealed only a negligible association with health outcomes (Violette et al., 2015), more recent trials demonstrate improved decision making and treatment selection, suggesting an emerging role for shared decision making. The available evidence suggests that interventions aimed at informing patients regarding the comparative effectiveness of prostate cancer management alternatives should include the influence of physician recommendations and family members' desires on patient decision making (Showalter et al., 2015). The urologist's recommendation for treatment, however, continues to have the most influence on decision making (Davison and Breckon, 2012).

Assessment of Prostate Cancer Risk

Tools for Risk Stratification

Risk assessment in prostate cancer is important from several perspectives. Accurately determining the risk of cancer mortality over time allows adequate decision making regarding necessity for therapy but also allows decisions regarding which treatment approaches may be reasonable options of consideration. Currently, the most acknowledged criteria used to risk-stratify prostate cancer are clinical stage, biopsy Gleason score, and pretreatment serum PSA level. No single criterion can precisely identify all men at high risk of disease progression and mortality with or without therapy. Although various risk classification systems have been developed, standardized criteria that define prostate cancer risk stratification are still lacking (D'Amico et al., 1998; Eberhardt et al., 2013; European Association of Urology, 2015; Heidenreich et al., 2011; Horwich et al., 2013; National Comprehensive Cancer Network, 2015; Roach et al., 2000; Thompson et al., 2007). This lack of consensus is a critical obstacle in patient counseling, evaluation of treatment outcomes, and design of clinical trials, as well as the establishment and appraisal of guidelines that include recommended staging protocols.

Definitions of Low, Intermediate, and High Risk

Among the large numbers of newly diagnosed prostate cancers that appear clinically indolent, those with unrecognized underlying aggressive biology continue to pose a challenge, regardless of chosen treatment strategy. A joint guideline from the AUA/ASTRO/SUO for clinically localized prostate cancer risk stratifies men with prostate cancer into very low, low, intermediate, and high risk (Sanda et al., 2018a). These guidelines do not substratify intermediate risk men into favorable and unfavorable, nor do they substratify high-risk men into high risk and very high risk as proposed by the NCCN (Table 153.1; Mohler et al., 2016). Men with low-risk and intermediate-risk prostate cancer, per National Comprehensive Cancer Network criteria, represent a broad range of disease aggressiveness, and understanding the optimal treatment strategies for these men continues to be a critical area of investigation.

TABLE 153.1

Risk Stratification and Staging Workup

NCCN RISK GROUP	CLINICAL/PATHOLOGIC FEATURES	IMAGING
Very low	• T1c AND • Gleason score ≤6/grade group 1 AND • PSA <10 ng/mL AND • Fewer than 3 prostate biopsy fragments/cores positive, ≤50% cancer in each fragment/core AND • PSA density <0.15 ng/mL/g	• Not indicated
• Low	• T1–T2a AND • Gleason score ≤6/grade group 1 AND • PSA <10 ng/mL	• Not indicated
• Favorable intermediate	• T2b–T2c OR • Gleason score 3+4=7/grade group 2 OR • PSA 10–20 ng/mL AND • Percentage of positive biopsy cores <50%	• Bone imaging: not recommended for staging • Pelvic ± abdominal imaging: recommended if nomogram predicts >10% probability of pelvic lymph node involvement
Unfavorable intermediate	• T2b–T2c OR • Gleason score 3+4=7/grade group 2 or Gleason score	• Bone imaging: recommended if T2 and PSA >10 ng/mL • Pelvic ± abdominal imaging:

	4+3=7/grade group 3 OR • PSA 10–20 ng/mL	recommended if nomogram predicts >10% probability of pelvic lymph
• High	• T3a OR • Gleason score 8/grade group 4 or Gleason score 4 + 5=9/grade group 5 OR • PSA >20 ng/mL	• Bone imaging: recommended • Pelvic ± abdominal imaging: recommended if nomogram predicts >10% probability of pelvic lymph
• Very high	• T3b–T4 OR • Primary Gleason pattern 5 OR • >4 cores with Gleason score 8–10/grade group 4 or 5	• Bone imaging: recommended • Pelvic ± abdominal imaging: recommended if nomogram predicts >10% probability of pelvic lymph

PSA, Prostate-specific antigen.

Risk group stratification may be useful in making decisions regarding the preferred management strategies as well as prognostic assessments. Worsening oncologic outcomes have been associated with increasing disease risk. For example, men with very-low–risk prostate cancer have been shown to be at significantly lower risk for adverse findings at surgery compared with those with low-risk disease (Tosoian et al., 2013). Favorable risk groups have been found to harbor adverse pathological features compared with those in the low-risk group that affect cancer progression and candidate selection for active surveillance (Aghazadeh et al., 2018; Gearman et al., 2018). Relative to high-risk prostate cancer, men with very high risk disease treated with radical prostatectomy have significantly worse pathological and oncologic outcomes and more frequently require additional therapies (Pompe et al., 2017). These observations, taken together, validate the risk stratification groups.

Gleason Scoring and Grade Groups

The Gleason scoring system was introduced in 1966 for the histologic assessment of prostate cancer aggressiveness and is based upon an assessment of the glandular patterns of cancer present in the specimen. The score is presented as a sum of the dominant pattern and the largest minority pattern present in the sample. Gleason initially described 5 patterns ranging from 1 to 5, with pattern 5 being the most poorly differentiated. In 2005 the International Society of Urologic Pathology (ISUP) recommended against the use of patterns 1 and 2, leaving a shortened scoring scale of 6 to 10 (Epstein, 2010; Epstein et al., 2005). In addition, the consensus recommended that a number of variant patterns previously graded as 3, and all cribriform patterns, should be considered pattern

4. In doing so, there has been an observation of Gleason scoring migration, with a greater number of cancers designated as Gleason score 3+4 or 4+3, as compared with historical cohorts. This migration has led to a reassessment of the accuracy of Gleason scoring in contemporary practice, with most such evaluations demonstrating improved prognostic accuracy (Billis et al., 2008; Epstein, 2010; Uemura et al., 2009). Although the grading system appears to be more prognostically accurate, it has created difficulty in comparing historical outcomes of treatment to contemporary cohorts, given the difference in what is meant by Gleason 3+3 and 3+4/4+3.

Given the difficulty of communicating prognosis to patients on a grading scale extending from 6 to 10, a, new prostate cancer grading scheme, consisting of grade groups, was proposed in 2013 (Pierorazio et al., 2013) and advocated by the ISUP in 2014 (Epstein et al., 2016) in an effort to better reflect and communicate true biologic aggressiveness and guide clinical management (Carter et al., 2012). The new prognostic grade groups use a scale of 1 to 5 with Gleason grade group (GGG) 1 consisting of Gleason 3+3, GGG 2 = 3+4, GGG 3 = 4+3, GGG 4 = 4+4, and GGG 5 = 4+5, 5+4, and 5+5. The Gleason grade group scheme has been investigated, and its correlation with prostate cancer–specific mortality has been validated (He et al., 2017; Loeb et al., 2016).

Epstein Criteria

Epstein et al. in 1994 developed PSA and needle biopsy-related criteria (PSA density < 0.15 ng/mL/g, absence of adverse pathological findings on biopsy (i.e., biopsy Gleason score ≤ 6), presence of prostate cancer in fewer than 3 cores (in 6-core biopsy samples), no more than 50% prostate cancer involvement in any of the cores for identifying insignificant prostate cancer (Epstein et al., 1994). According to these criteria the accuracy of predicting organ-confined (<pT3a stage) tumors with volume less than 0.5 mL and without high-grade components is 79%. Ten years later, Bastian et al. (2004) revised these criteria and reported a higher predictive accuracy, up to 83.9%. The Epstein Criteria remains one of the most commonly used tools for predicting insignificant prostate cancer and determining candidates for active surveillance (Tosoian et al., 2015).

The biopsy findings (Gleason score; the number of cores containing cancer; the distribution and volume of cancer in the biopsy cores; the presence of perineural space invasion, lymphovascular invasion, ductal, signet ring, or neuroendocrine differentiation) also correlate with cancer aggressiveness and the likelihood of the cancer's being organ confined.

Staging

Guidelines for initial diagnostic imaging in the newly diagnosed prostate cancer patient vary considerably (American Urological Association, 2007; Sanda et al., 2017). Although most definitions support radionuclide bone scan for the initial staging of high-risk prostate cancer, not all specifically address imaging for soft tissue metastases (Briganti et al., 2010; Crawford et al., 2014). Those that do commonly endorse pelvic CT or MRI. **Current NCCN guidelines recommend the use of technetium-99m bone scan and cross-sectional imaging (CT or MRI) among high-risk and unfavorable intermediate-risk men deemed to be at high risk for occult metastasis on the basis of clinical parameters or nomograms** (see Table 153.1). In cases of equivocal bone scans, PET/CT or MRI have been endorsed by several professional organizations.

In 2012 the American Society of Clinical Oncology (ASCO) and in 2013 the American Urological Association highlighted the need to reduce the overuse of imaging in staging low-risk prostate cancer, launching the “Choosing Wisely” campaign. Several studies show poor compliance with these guidelines, whereby men with low-risk prostate cancer continue to undergo guideline-discordant imaging, whereas men with high-risk disease paradoxically have lower rates of guideline-adherent imaging (Makarov et al., 2012). These findings suggest that imaging is often underused in men with high-risk prostate cancer who could potentially benefit from it. The guideline-discordant association between higher imaging rates and increasingly aggressive disease risk suggest that established guidelines have had limited impact on the high rates of inappropriate imaging use. **Although the publication of guidelines seems to lower national rates of inappropriate imaging, it also lowers the rate of appropriate prostate cancer imaging** (Abraham et al., 2007).

Bone scan has been the most widely used method for evaluating bone metastases of prostate cancer and remains the current standard imaging test for initial prostate cancer staging, recurrence, and metastatic disease. This technique is clinically easy to interpret, relatively cost effective, and widely available. Because of its relatively low specificity, however, patients with equivocal findings often require additional imaging modalities. The diagnostic yield of a bone scan is significantly influenced by the PSA level, clinical stage, and Gleason score (McArthur et al., 2012).

CT has a very limited role for local staging of high-risk prostate cancer because it generally does not visualize early metastases. The separation between the prostate and the levator ani muscle is poorly defined on CT, and intraprostatic anatomy is not well demonstrated. CT may be useful as a baseline examination in high-risk patients with grossly advanced local disease (gross extraprostatic disease, gross seminal vesicle invasion [SVI], or invasion of the surrounding structures) with resultant hydronephrosis or urinary retention. A fundamental shortcoming of CT in detecting lymph node metastases is its inability to detect architectural changes within normal-sized (<10 mm) lymph nodes. Although CT has limitations in detecting metastatic prostate cancer to the lymph nodes, **it remains the guideline-endorsed imaging choice for staging in men at risk for lymph node involvement** (Bekelman et al., 2018; Carroll et al., 2016; Sanda et al., 2018a).

Prostate magnetic resonance imaging (MRI) is increasingly used in the diagnostic and evaluation pathway for prostate cancer (Bjurlin et al., 2014; Siddiqui et al., 2015). Local staging includes assessment of extraprostatic extension (EPE), which affects surgical planning and aids in assessing risk for local symptoms arising from tumor volume and bladder neck invasion, along with seminal vesicle invasion (SVI). For identifying EPE and SVI, MRI is the only examination with sufficient accuracy to be used in clinical practice given its combination of high spatial and contrast resolution. Historically, assessment for EPE on MRI was based on T2-weighted imaging (T2WI), which provides the best spatial resolution of the MR sequences typically employed. The identification of EPE on T2WI alone is dependent on the amount of EPE present. Gross extension or disruption of the capsule is highly predictive of EPE, but more subtle findings such as irregularity or bulging of the "capsule" have a lower predictive value. In general, MRI is poor for the detection of focal EPE, but subtle findings, such as linear length of capsular contact at the region of suspicion, may improve the pretreatment prediction of the likelihood of EPE (Rosenkrantz et al., 2013, 2016). Accuracy for more subtle EPE is improved when T2WI is combined with diffusion-weighted imaging (DWI) (Chong et al., 2014) or dynamic contrast-enhanced (DCE) imaging (Futterer et al., 2005) primarily because these additional sequences improve dominant tumor localization, which in turn helps predict presence of EPE. However, uncertainty remains because these ancillary sequences have lower spatial resolution than T2WI.

Currently, multiparametric MRI sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) in determining EPE in high-risk PCa has been reported to be 65%, 73%, 89%, and 38%, respectively (Somford et al., 2013). Although the suboptimal sensitivity has limited application of MRI for local staging in some practices, a high PPV is important in high-risk patients because knowledge of the site of EPE may help reduce the risk of a positive surgical margin. SVI has also been evaluated largely using T2WI. SVI appears as a T2-hypointense mass within the seminal vesicles, typically in direct contiguity with tumor in the prostate base. Studies show improved accuracy for detecting SVI when combining T2WI with DWI. High sensitivity and specificity for SVI, 83% and 99% respectively, has been observed using MRI in recent reports (Cornud et al., 2012). Knowledge of EPE and SVI is critical for appropriate patient counseling as well as treatment selection and planning as it is associated with worsened oncologic outcomes and early biochemical recurrence.

Interest in PET imaging in prostate cancer is increasing because it provides more functional information than other imaging modalities and can detect metastases (Bjurlin et al., 2015, 2018). In PET imaging, radiolabeled biomolecules pertinent to cellular processes are used to detect metabolic activity or cell surface molecules that are usually associated with cancer. PET imaging is conventionally combined with CT or MRI sequences to improve anatomic localization of abnormal tracer uptake. Clinical experience with PET in prostate is increasing, although PET is not approved for primary staging of prostate cancer in the United States. Currently none of the existing PET agents are recommended in practice guidelines for localized prostate cancer diagnosis; however, among them, prostate-specific membrane antigen-based tracers seem to hold the most promise based on sensitivity and specificity (Han et al., 2018). Given its performance characteristics, PET may also be potentially useful for identifying patients suitable for active surveillance, for accurate preradical prostatectomy/preradiation therapy staging.

Nomograms for Prediction of Stage

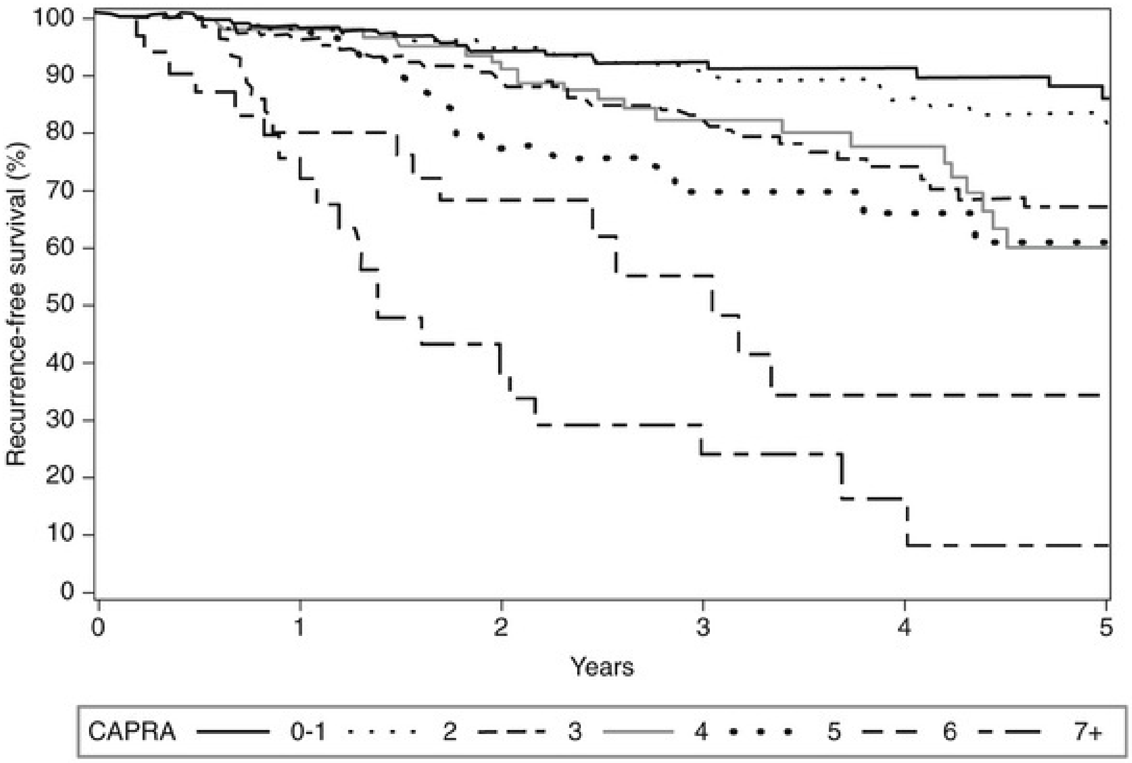
Early in the PSA era, prognostic assessment before surgery was often based solely on the PSA level. Because of the realization that Gleason score and clinical stage often were disparate with the PSA level alone, Partin, et al. (1993) created predictive nomograms derived from these three variables that allowed prediction of stage at time of radical prostatectomy. Widely used, these nomograms, commonly referred to as the Partin tables, were validated on a multi-institutional cohort demonstrating relative accuracy of prediction 72.4% of the time (Partin et al., 1997). The tables have been tested in other populations and appear to be generalizable to other geographic and ethnic populations

(Bianco et al., 2003; Blute et al., 2000; Eschwege et al., 2003; Karakiewicz et al., 2005; Naito et al., 2008). The tables are derived from the cumulative experience of urologists performing radical prostatectomy at John Hopkins University and have been updated periodically to reflect the evolving clinical characteristics of the cohort (Makarov et al., 2007; Partin et al., 2001).

Since the inception of the Partin tables, a multitude of clinical nomograms have been described for predicting organ-confined disease within the pretreatment population (Briganti et al., 2006a, 2006b). Most of these nomograms use similar clinical variables to the Partin tables, or incorporate additional clinical variables such as age, digital rectal exam, PSA density, or percent cancer involvement on biopsy, and are validated on other clinical cohorts.

Risk Stratification Nomograms

In addition to prediction of radical prostatectomy pathologic outcome, a number of instruments have been developed to predict clinical outcomes after treatment, including relapse and survival after prostatectomy (Briganti et al., 2006b; Kattan et al., 1997, 1998). The initial description of such a nomogram by Kattan et al. (1998) incorporated PSA, clinical stage, and Gleason score and achieved an overall diagnostic accuracy of 0.79 as measured by area under the receiver operating characteristic curve (predicted probability vs. actual outcome). The UCSF Cancer of the Prostate Risk Assessment (CAPRA) score was developed for the prediction of predicting clinical outcomes using age, PSA level, clinical stage, biopsy Gleason score, and percentage of positive biopsy cores. In its initial description, the UCSF-CAPRA score was able to widely segregate risk from a 5-year recurrence-free survival of 85% among low-risk to 8% among high-risk patients (Fig. 153.2; Cooperberg et al., 2005). This stratification scheme has subsequently been shown to additionally predict prostate-cancer-specific mortality independently of the treatment given (Cooperberg et al., 2009).



Survival curves for 5-year recurrence-free survival among patients with each UCSF-CAPRA score

FIG. 153.2 University of California, San Francisco (UCSF) Cancer of the Prostate Risk Assessment Score (CAPRA). (Reproduced from Cooperberg MR, Pasta DJ, Elkin EP, et al.: The University of California, San Francisco Cancer of the Prostate Risk Assessment score: a straightforward and reliable preoperative predictor of disease recurrence after radical prostatectomy. *J Urol* 173[6];1938–1942, 2005.)

Other parameters, such as the extent of cancer in needle biopsy, prediagnosis PSA velocity, PSA doubling time, or the presence of a tertiary Gleason pattern, have been explored as a means of enhancing risk stratification (Hattab et al., 2006; O'Brien et al., 2009; Ravery et al., 2000). The applicability of some of these parameters remains unclear because they are not routinely collected in clinical practice. Additional nomograms have been created to inform treatment decision making for men contemplating active surveillance (Kattan et al., 2008), radical prostatectomy (Stephenson et al., 2006), neurovascular bundle preservation, or omission of pelvic lymph node dissection during radical prostatectomy, brachytherapy, or external beam radiation therapy (Brockman et al., 2015; Kattan et al., 2003). Biochemical progression-free survival can be reassessed postoperatively using nomograms of age, diagnostic serum PSA, and pathological grade and stage. Potential success of adjuvant or salvage radiation therapy after unsuccessful radical prostatectomy can also be assessed using a nomogram.

Prostate Magnetic Resonance Imaging in Risk Assessment

Contemporary prostate MRI interpretation of the prostate is reported using the Prostate Imaging Reporting and Data System (PI-RADS version 2), which provides the minimum acceptable technical standards for MR image acquisition and suggests a structured method for prostate MRI reporting and conveyance of the level of suspicion for clinically significant prostate cancer (Weinreb et al., 2016). The PI-RADS score, or MRI suspicion score before the advent of PI-RADS, along with the apparent diffusion coefficient (ADC), measured on diffusion-weighted imaging, has been shown to correlate with clinical outcomes and thus can be used as a risk stratification tool (De Cobelli et al., 2015; Fuchsjager et al., 2010; Giles et al., 2011; Henderson et al., 2016; Ho et al., 2016; Lee et al., 2016; Park et al., 2011, 2014, 2016; Riaz et al., 2012; Rosenkrantz et al., 2015; Tamada et al., 2017; van As et al., 2009; Westphalen et al., 2011; Yamaguchi et al., 2016; Yoon et al., 2017). Recent data have explored the value of MRI in monitoring tumors in patients on an active surveillance protocol. In patients with low-risk, localized disease, tumor ADC on DWI may be a useful marker of prostate cancer progression and may help to identify patients who stand to benefit from radical treatment (Giles et al., 2011). As a preoperative imaging tool, tumor ADC and PI-RADS may also be useful to predict biochemical recurrence after radical prostatectomy and radiation therapy (Ho et al., 2016; Park et al., 2014; Westphalen et al., 2011). MRI data improve the prediction of biochemical failure within nomograms after external-beam radiation therapy (EBRT) (Westphalen et al., 2011). Pretreatment MRI findings have also been found to predict for biochemical recurrence in intermediate- and high-risk prostate cancer patients treated with combination brachytherapy and external-beam radiotherapy (Riaz et al., 2012).

MRI may add utility as a method for predicting treatment outcomes and progression on active surveillance. MRI, in conjunction with traditional clinical parameters and secondary biomarkers, may allow more accurate risk stratification and assessment of need for repeat prostate biopsy among men with discordant prostate biopsy and MRI findings. **As such, prostate MRI may aid in risk assessment of patients newly diagnosed with prostate cancer and allow improved decision making with regard to need for therapy, likelihood of treatment failure, and need for repeat biopsy for further risk assessment.**

Genomic Tests for Risk Stratification

Risk stratification based on traditional clinical parameters can stratify patients' risk of prostate cancer progression with relatively good reliability, but substantial heterogeneity persists within standard risk groups. With improved approaches to biomarker research, combined with lower cost and more efficient techniques, the potential of a personalized genomic approach for clinical decision making has recently been made possible.

An increased understanding of prostate cancer biology has led to the development of molecular tests specifically tailored to prostate cancer. Genomic testing has been shown to provide additional prognostic information, particularly when taken in conjunction with risk groups based on stage, Gleason score, and serum PSA. New molecular biomarkers are commonly divided into liquid and tissue (obtain from prostate biopsy) biomarkers. Compared with tissue-based assays, liquid biomarkers have minimal risks, as transrectal prostate biopsy carries with it the potential risk of infection and sepsis. Liquid biopsies commonly include Prostate Health Index (PHI) (Catalona et al., 2011; de la Calle et al., 2015), 4Kscore test (Parekh et al., 2015; Punnen et al., 2017), prostate cancer antigen 3 (PCA3) (Wu et al., 2012), Mi-Prostate Score (Salami et al., 2013), Select MDx (Van Neste et al., 2016), and ExoDx Prostate Intelliscore (Nilsson et al., 2009). Although significant strides have been made in the development of liquid biomarkers, tissue-based assays remain the gold standard for accurately representing the tumor environment in prostate cancer. Confirm MDx (Stewart et al., 2013), Polaris (Cuzick et al., 2011), Decipher (Erho et al., 2013), and OncotypeDx GPS (Klein et al., 2014) are now recommended by the Molecular Diagnostic Services Program, which aims to identify and establish coverage and insurance reimbursement for molecular diagnostic tests.

There is disagreement about whether and how genomic tests should be employed in selecting a treatment approach for men with prostate cancer. Consensus-based guidelines from the NCCN state that molecular testing should be considered for men who are potential candidates for active surveillance and have low-risk or favorable intermediate-risk disease with a life expectancy more than 10 years. However, 2018 guidelines from the American Urological Association (AUA)/American Society for Radiation Oncology (ASTRO)/Society of Urologic Oncology (SUO) for management of clinically localized prostate cancer, which were endorsed by the American Society of Clinical Oncology (ASCO), state that among most low-risk prostate cancers, tissue-based genomic biomarkers have not shown a clear role in the selection of candidates for active surveillance (Bekelman et al., 2018; Sanda et al., 2018a,b).

Although current data suggest that molecular tests can add additional, independent prognostic information that may aid in risk stratification of localized prostate cancer, head-to-head comparisons across multiple different patient populations with specifically designed, clinically relevant end points must be undertaken, taking into account relative effectiveness and cost. Furthermore, molecular prognostic studies are highly dependent on the tissue collected, particularly in the pretreatment setting or when extirpative treatment is not planned. With further clinical experience, these molecular prognostic tests may further risk stratify untreated and treated men with localized prostate cancer.

Selection of Treatment: Comparative Studies

Oncologic Outcomes

In offering patients recommendations regarding the relative efficacy of individual treatment options, there is a paucity of high-quality comparative data, with the majority of such studies carrying significant limitations to be considered in interpretation of results. The difficulty in comparing options, together with the high prevalence of the disease, led the Institute of Medicine to include localized prostate cancer among the top 25 priority conditions for future comparative effectiveness research (Institute of Medicine of the National Academies, 2009). A significant challenge in characterization of oncologic outcomes after treatment is the myriad of used end points and their varying definitions.

The use of biochemical-free survival as an oncologic end point is problematic for many reasons. First, there is tremendous variation in the definition of biochemical-free survival. Second, variation in posttreatment PSA kinetics may also affect observed differences in rates of biochemical-free survival after radical prostatectomy and radiation therapy because the cytotoxic effects of radiation therapy may take several months or years, and it does not eliminate all prostatic sources of PSA. Last, the differential use of ADT, which is especially common among high-risk radiation patients, may delay time to biochemical progression. Cancer-specific and overall mortality are generally considered to be the most valid end points for comparisons of efficacy but require a protracted follow-up given the known long lead-time from diagnosis to death. In some studies, poor candidate selection may lead to high rates of non-oncologic death, impairing the ability to assess the impact of treatments on cancer-specific survival. Taken together, direct comparisons between oncologic outcomes and various trials are challenging and underscore the importance of contextualizing the study question before making inferences about available data.

Comparative Population-Based Studies

Several population-based analyses have evaluated the comparative effectiveness of radiation therapy and radical prostatectomy in localized disease. In a large population-based trial of more than 34,000 Swedish men with localized prostate cancer, the risk of prostate cancer- specific mortality was higher among radiation therapy patients as compared with radical prostatectomy patients (HR 1/4 1.76 [95% CI 1.49–2.08]) (Fig. 153.3; Sooriakumaran et al., 2014). A similar study using data from CaPSURE found a higher prostate cancer-specific mortality rate after adjusting for age and disease risk (HR 1/4 2.21; 95% CI 1.50–3.24) (Cooperberg et al., 2010) as have several SEER-based investigations (Abdollah et al., 2011a,b; Liu et al., 2008). In a study of more than 1500 men with 15 years of follow-up from the Prostate Cancer Outcomes Study, radical prostatectomy was associated with a statistically significant overall (HR = 0.60; 95% CI 0.53–0.70) and disease-specific (HR = 0.35; 95% CI 0.26–0.49) survival advantage (Hoffman et al., 2013). However, well-known biases frequently confound the interpretation of observational comparative-effectiveness studies. Selection, detection, and confounding bias can produce systematically distorted results contradictory to randomized trial studies (Albertsen, 2016; Giordano et al., 2008).

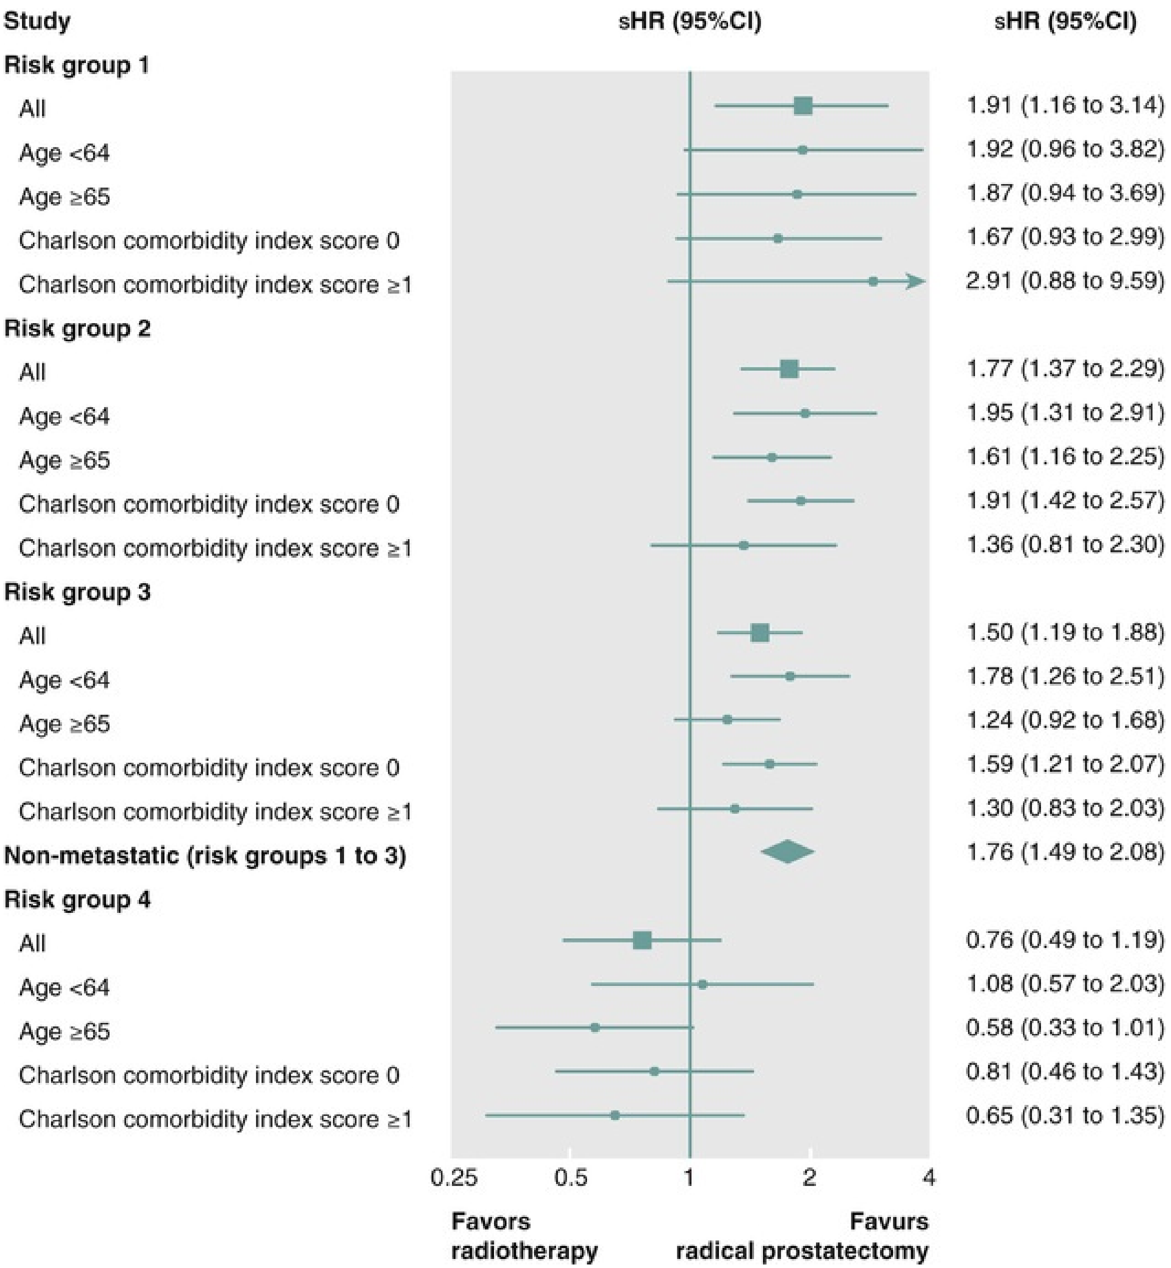


FIG. 153.3 Forest plot depicting propensity score adjusted subdistribution hazard ratios (sHR) for radiotherapy versus radical prostatectomy for cancer-specific mortality stratified by risk group, and substratified by age and Charlson comorbidity index score. (Data from Sooriakumaran P, Nyberg T, Akre O, et al.: Comparative effectiveness of radical prostatectomy and radiotherapy in prostate cancer: observational study of mortality outcomes. *BMJ* 348:g1502, 2014.)

Scandinavian Prostate Cancer Group Study Number 4.

The Scandinavian Prostate Cancer Group Study Number 4 (SPCG-4) is a randomized trial of radical prostatectomy versus watchful waiting in men with localized prostate cancer (Holmberg et al., 2002). The SPCG-4 was the first to publish a randomized intention-to-treat analysis comparing watchful waiting and radical prostatectomy using informative clinical end points such as overall and cancer-specific survival. Furthermore, the SPCG-4 offered the long-term follow-up necessary to characterize between-group differences in survival and employed rigorous study design methods such as blinded histopathologic review. However, because this trial enrolled men predominantly during the pre-PSA era, nearly 90% of the 695 participants harbored palpable disease. Although a number of important observations regarding the comparative effectiveness of radical prostatectomy in the treatment of localized prostate can be made from the SPCG-4 data this trial does not reflect current prostate cancer screening, detection, and treatment paradigms. During 23.2 years of follow-up, 200 of 347 men in the surgery group and 247 of the 348 men in the watchful-waiting group died (Bill-Axelson et al., 2014). Of the deaths, 63 in the surgery group and 99 in the watchful-waiting group were due to prostate cancer; the relative risk was 0.56 (95% CI 0.41–0.77; $P = 0.001$), and the absolute difference was 11.0 percentage points (95% CI 4.5–17.5). The number needed to treat to prevent 1 death was 8. The benefit of surgery with respect to death from prostate cancer was largest in men younger than 65 years of age (relative risk, 0.45) and in those with intermediate-risk prostate cancer (relative risk, 0.38). However, radical prostatectomy was associated with a reduced risk of metastases among older men (relative risk, 0.68; $P = 0.04$).

PIVOT.

PIVOT was a prospective randomized trial designed to address whether radical prostatectomy, as compared with observation, improved overall survival and prostate cancer-specific survival in men diagnosed with prostate cancer during the PSA era (Wilt et al., 2012). Initially designed to randomize 2000 men, the study recruited only 731 men, which was addressed by attempting to lengthen follow-up. At a median follow-up of 10 years, there was no difference in either overall or prostate-cancer specific mortality among the two treatment arms. Multivariate analysis showed that the effect of treatment on mortality did not vary according to age, race, performance status, or comorbid conditions. Subgroup analysis found no benefit of surgery for men with low-risk disease; however, radical prostatectomy reduced all-cause mortality in men with PSA values greater than 10 ng/mL and approached significance in those with intermediate and high-risk tumors. Notably, there was a statistically significant reduction in bone metastases in patients treated by radical prostatectomy (4.7%) versus expectant management (10.6%), which became more robust in patients with PSA exceeding 10 ng/mL and in those with intermediate- and high-risk disease.

PIVOT must be viewed in the light of its limitations. When enrollment goals were not met, the power calculation for the study was reformulated with lengthened follow-up, leaving a 91% power to detect a 25% relative reduction in all-cause mortality. The PIVOT study remained underpowered with the final enrollment of only 731 patients; it would have required 1200 patients to be adequately powered to detect a 25% relative reduction in overall mortality (Thompson and Tangen, 2012). Another shortcoming of the study is the large proportion of patients, nearly 20%, who were nonadherent to their assigned treatment group, thus even further diminishing the capacity to identify a treatment effect. In addition, only 10% of the men in their study were under the age of 60, therefore leaving the question of surgical management in a younger, healthier cohort unaddressed.

The follow-up of the original PIVOT analysis was published in 2017, after 19.5 years of follow-up, demonstrating an absolute risk reduction (ARR) of 5.5% (95% CI −1.5%–12.4%; $P = 0.06$) for all-cause mortality (61.3% vs. 66.8%) through prostatectomy (Wilt et al., 2017). An ARR of 4.0% (95% CI −0.2%–8.3%; $P = 0.06$) was found for prostate cancer-specific mortality (7.4% vs. 11.4%). On subgroup analysis, surgery reduced all-cause mortality among men with intermediate-risk disease (ARR = 14.5%; 95% CI 2.8%–25.6%). By contrast, no benefit was seen in the low- or high-risk groups. Although surgery reduced the need for treatment of progressive disease, there were increased incidences of therapy-related long-term complications such as urinary incontinence and erectile and sexual dysfunction.

One of the major concerns regarding the PIVOT study design was that the inclusion criterion for the study was life expectancy of more than 10 years. However, according to the analysis of all-cause mortality after 10 years of follow-up, nearly 40% of the study population had died, with only approximately 5% from prostate cancer. After 15 years, up to 60% had died, with approximately 10% from prostate cancer. These considerations suggest poor risk assessment at baseline inclusion and lessen the impact of the study. Since the design of the study, it is now well understood that patients with low-risk prostate cancer and comorbidities do not benefit within 10 years from radical interventions.

Prostate Cancer Outcomes Study.

To determine the relative rate of mortality in men undergoing radical prostatectomy or radiotherapy, an observational cohort from the population-based Prostate Cancer Outcomes Study was conducted, which included men aged 55 to 74 years diagnosed with localized prostate cancer between October 1994 and October 1995 who underwent either radical prostatectomy ($n = 1164$) or EBRT ($n = 491$) within 1 year of diagnosis. Patients were followed until death or study end. Overall and disease-specific mortality were assessed with multivariable analyses with propensity scores. After 15 years of follow-up, there were 568 deaths, including 104 from prostate cancer. Radical prostatectomy was associated with statistically significant advantages for overall (hazard ratio [HR] = 0.60; 95% CI 0.53–0.70; $P < 0.0001$) and disease-specific mortality (HR = 0.35; 95% CI 0.26–0.49; $P < 0.0001$). Although this study supports a long-standing idea that the benefit of surgery over radiation is greatest in younger men and those with lower disease risk features, it also supports an improved survival in older men and those with high-risk disease. In all subgroups differences in overall and cancer-specific mortality were recorded as early as 3 years after therapy. These results are inconsistent with early stage disease. Some of the findings are not intuitive and suggest the potential for selection bias in the prostatectomy cases despite the propensity scoring technique. For example, among men with low-risk disease the overall mortality was decreased in surgically treated patients compared with radiated patients, although cancer-specific mortality did not differ. This finding may be attributable to differences in the groups not recorded in the existing data set, such as disease volume, true stage and unrecorded predictors of non-oncologic mortality.

ProtecT.

The Prostate Testing for Cancer and Treatment (ProtecT) trial was a randomized trial of prostatectomy, external-beam radiation with androgen deprivation, or prostate-specific antigen–based active monitoring (Hamdy et al., 2016). Between 1999 and 2009, a total of 82,429 men 50 to 69 years of age received a PSA test; 2664 received a diagnosis of localized prostate cancer, and 1643 agreed to undergo randomization to active monitoring (545 men), surgery (553 men), or radiotherapy (plus 3–6 months of androgen deprivation therapy, 545 men). The primary outcome was prostate-cancer mortality at a median of 10 years of follow-up. Secondary outcomes included the rates of disease progression, metastases, and all-cause death. In total, 62% of eligible men accepted randomization, comprising a cohort with mostly low- to intermediate-risk tumors. Rates of immediate crossover were substantial. Only 88%, 71%, and 74% of the men assigned to monitoring, prostatectomy, and radiation, respectively, received their assigned management. A quarter of the men embarking on monitoring were treated within 3 years, and more than half within the first 10 years. The primary outcome of prostate cancer mortality was not different between the three arms at a median follow-up of 10 years. However, the incidence of metastases was higher in the active monitoring group. The majority of included patients had a low PSA and Gleason 6 tumors (grade group 1). Because the chance of low-risk patients dying from prostate cancer within 10 years is very low, longer follow-up may be needed to draw firm conclusions. The mortality in the study was approximately 1%, which is low in comparison with the predicted mortality of 15% at the time the study was designed, thereby reducing the power of the study to assess its intended purpose.

Functional Outcomes

Maximizing quality of life for patients with prostate cancer is a critical goal of active management and shared decision making. Because differences in oncologic outcomes for individual treatment approaches are controversial at best, patients must thoroughly consider acute and long-term effects on quality of life in choosing treatment modality. These quality-of-life concerns should be discussed in detail with patients during pretreatment counseling (Lardas et al., 2017).

Historically comparisons of functional outcomes of surgery and radiation have been based on large, single institution centers of excellence, thereby decreasing the generalizability of the findings and minimizing the accuracy of the comparison resulting from wide selection biases. Efforts to compare outcomes from large population data sets have similarly been limited by the inadequacy of the recorded data fields, inaccuracy of recording instruments, and wide skill sets and therapeutic approaches of the represented operators. Several large comparative trials have now been published, allowing new insight into the functional outcomes after prostate cancer treatment (see Table 2 in https://jamanetwork.com/journals/jama/fullarticle/2612617).

Prostate Cancer Outcomes Study.

Urinary, bowel, and sexual function at short and intermediate term as well as up to 15 years after prostatectomy or EBRT have been reported in men from the population-based Prostate Cancer Outcomes Study (PCOS), diagnosed with localized cancer in the mid-1990s (Resnick et al., 2013). Patients undergoing prostatectomy were more likely to have urinary incontinence than were those undergoing radiotherapy at 2 years (odds ratio, 6.22; 95% CI 1.92–20.29) and 5 years (odds ratio, 5.10; 95% CI 2.29–11.36) of follow-up. However, no significant between-group difference in the odds of urinary incontinence was noted at 15 years. Similarly, although patients undergoing prostatectomy were more likely to have erectile dysfunction at 2 years (odds ratio, 3.46; 95% CI 1.93–6.17) and 5 years (odds ratio, 1.96; 95% CI 1.05–3.63), no significant between-group difference was noted at 15 years. Patients undergoing prostatectomy were less likely to have bowel urgency at 2 years (odds ratio, 0.39; 95% CI 0.22–0.68) and 5 years (odds ratio, 0.47; 95% CI 0.26–0.84), again with no significant between-group difference in the odds of bowel urgency at 15 years. These data, taken together, appear to suggest patients in the PCOS had significant declines in sexual and urinary function over the duration of the study. The possible reasons for the first finding include declining sexual interest with age, acceptance of sexual dysfunction over time, or both. Likewise, the causes of urinary decline probably include advancing age and additional cancer treatments.

ProtecT.

Patient-reported outcomes from the ProtecT trial have shown that of the three treatments (active monitoring, radical prostatectomy, and radical radiotherapy with hormones), prostatectomy had the greatest negative effect on sexual function and urinary continence, and although there was some recovery, these outcomes remained worse in the prostatectomy group than in the other groups throughout the trial (Donovan et al., 2016). The negative effect of radiotherapy on sexual function was greatest at 6 months, but sexual function then recovered somewhat and was stable but below baseline thereafter. Radiotherapy had little effect on urinary continence. Sexual and urinary function declined gradually in the active-monitoring group. Bowel function was worse in the radiotherapy group at 6 months than in the other groups but then recovered somewhat, except for the increasing frequency of bloody stools. Bowel function was unchanged in the other groups. Urinary voiding and nocturia were worse in the radiotherapy group at 6 months but then recovered and were similar to the other groups after 12 months. Effects on quality of life mirrored the reported changes in function.

No significant differences were observed among the groups in measures of anxiety, depression, or general health-related or cancer-related quality of life.

Comparative Effectiveness Analysis of Surgery and Radiation.

Similar outcomes have been reported from the Comparative Effectiveness Analysis of Surgery and Radiation (CEASAR) study, a prospective, population-based, observational study that enrolled men with localized prostate cancer in 2011 and 2012 (Tyson et al., 2018). Low-risk EBRT patients reported 3-year sexual function scores 12 points higher than those of low-risk radial prostatectomy (RP) patients (RP, 39 points [95% CI 37–42] versus EBRT, 52 points [95% CI 47–56]; $P < 0.001$). The difference in 3-year scores for high-risk patients was not clinically significant (RP, 32 points [95% CI 28–35] vs. EBRT, 38 points [95% CI 33–42]; $P = 0.03$). However, with a commonly used binary definition of sexual function (erections firm enough for intercourse), no major differences were noted between RP and EBRT at 3 years of follow-up, across low-, intermediate-, and high-risk disease strata. These data have been updated to include functional outcomes of men on active surveillance. In this cohort of men with localized prostate cancer, 3 years after treatment, radical prostatectomy was associated with a greater decrease in sexual function and urinary incontinence than EBRT or active surveillance and was associated with fewer urinary irritative symptoms than active surveillance; however, no meaningful differences existed in either bowel or hormonal function beyond 12 months or in in other domains of health-related quality-of-life measures (Barocas et al., 2017).

Open versus Robotic Prostatecomy.

One randomized controlled phase III trial has been published comparing robotic-assisted laparoscopic and open radical prostatectomy, demonstrating the two techniques yield similar functional outcomes at 12 weeks (Yaxley et al., 2016). Robot-assisted radical prostatectomy has, however, been shown to improve functional and oncologic outcomes in a single surgeon's learning curve (Thompson et al., 2018). In an analysis of community-based outcomes, most patients experienced changes in urinary and sexual quality of life in the first 3 years after prostatectomy. The pattern of recovery over time was similar between open and robotic-assisted groups. The authors suggested patients should not expect different oncologic or quality-of-life outcomes based on surgical approach (Herlemann et al., 2018). Robot-assisted surgery also has been noted to facilitate easier identification of nerve preservation planes during radical prostatectomy as well as wider dissection for pT3 cases (Sooriakumaran et al., 2018), but such observations may reflect surgeon bias.

Patient Counseling: a Stepwise Decision Approach

In considering the management of newly diagnosed prostate cancer, men often become confused and anxious because of the multitude of options available to them and the conflicting information presented by individual treating physicians. Physicians may have trouble in offering objective advice regarding therapy because of the paucity of direct comparative data. **In approaching the newly diagnosed prostate cancer patient, using a methodical stepwise approach in considering the patient and presenting options to the patient can reduce confusion and anxiety** (Fig. 153.4). Through presentation of the relevant aspects of decision making, the patient is empowered to make an informed decision with regard to treatment necessity and treatment type. Patients are typically confronted with a decision about in which domain they are most willing to take on risk. In deciding between management strategies, the divergent risks are often those related to oncologic control/cancer mortality, and those related to treatment side effects and quality of life. As such, an approach of reviewing all options as a menu of choices is often without context and provides confusion because the goals of individual management strategies may be different.

FIG. 153.4 Patient counseling in localized prostate cancer: a stepwise decision approach. *EBRT,* External-beam radiation therapy; *SBRT,* stereotactic body radiation therapy.

Decision One: Observation versus Active Treatment

The stepwise approach first asks whether observation or treatment is the best first step (see Fig. 153.4). In counseling patients in this regard, clinicians should make a distinction between observation and active surveillance, with the latter being a strategy of active monitoring through repetitive testing and the latter being a decision to passively monitor for symptomatic progression only. The goal of active surveillance is to observe the patient until a time that clear evidence of need for treatment arises. In this regard, for many younger men, it is a deferral of treatment. In the case of observation, or non-treatment, the patient and the physician agree to take on the potential risk of disease progression and mortality, with plan for treatment typically only at the time of symptoms or extensive metastatic progression. In practice, many patients are monitored by a combination of these strategies, without a clearly established goal; currently there is no consensus regarding the optimal method of monitoring among surveillance cohorts (Loeb et al., 2016).

Among men newly diagnosed, the option of observation is most frequently employed among those men who are deemed to be at low risk of prostate cancer death because of competing risks for mortality and prolonged lead time in disease progression. As such, potentially curative treatment is not considered in this group because it has a low likelihood of improving longevity. In these men, follow-up generally consists of periodic PSA testing to assess the rapidity of disease progression, clinical exam, and selective use of imaging to monitor disease progression. Although curative-intent therapy is typically not used, carefully timed intervention, to avoid disease-related morbidity, remains desirable. At time of symptomatic progression, androgen-deprivation remains the mainstay of therapy, with use of palliative radiotherapy and surgery reserved for disease refractory to systemic intervention.

Contrarily, men choosing to initiate a strategy of active surveillance or monitoring of the disease are typically men with a reasonable expectation of prolonged longevity and limited comorbidities, demonstrated to have low clinical risk for metastatic progression based upon disease characteristics. In these men, the goal of management is often deferral of treatment until a time when progression of disease risk becomes evident. **Although its safety is now well demonstrated in long-term follow-up, men choosing active surveillance**

must feel comfortable with some uncertainty with regard to cancer outcome in exchange for maximal preservation of quality of life. Men must understand a critical need for adherence to follow-up and have a willingness to proceed with treatment at the time of predetermined signs of disease progression. If the uncertainty of surveillance is anxiety provoking for the patient or his family, treatment should be considered. Importantly, men with intermediate- or high-risk disease should be strongly discouraged from surveillance, although increasing age and comorbidity, limiting the certainty of prolonged longevity, may allow consideration of surveillance in men with higher-risk disease features.

Current recommendations from the AUA, ASTRO, SUO, and NCCN endorse the use of active surveillance in men with low-risk disease, and its use has increased over time (Filson et al., 2014, 2016; Loeb et al., 2017, 2018). Specifically, **surveillance should be recommended as the best care option for men with very low risk and the preferable care option for most low-risk, localized prostate cancer.** Although this strategy is widely endorsed, one of the limitations in application includes a 25% to 45% chance of occult high-grade cancer among men diagnosed with low-grade disease by systematic biopsy, lack of consensus regarding appropriate monitoring techniques, declining adherence to surveillance protocols over time (Bokhorst et al., 2015; Loeb et al., 2015, 2016), and unclear trigger points for intervention during the course of surveillance. Despite these limitations, clinical outcomes have been favorable, and this may be explained by the fact that most occult upgrading is to grade group 2 (Gleason 3 +4), which may carry relatively low metastatic potential over the first decade of follow-up. On this basis, there has been a growing interest in considering men with low-volume Gleason grade group 2 prostate cancer for surveillance. However, there remains little consensus in this regard: the presence of any Gleason 4 pattern cancer has been demonstrated to confer an increased risk of eventual metastasis (Klotz et al., 2015). Thus the goals of surveillance include proper candidate selection through baseline risk assessment, monitoring for disease progression over time, and judicious implementation of treatment when appropriate.

Baseline risk stratification has suffered from the inaccuracies of standard biopsy techniques. In this regard risk assessment may be refined through application of MRI and MRI-targeted biopsy in selection of candidates for inclusion. MRI has recently been incorporated into many active surveillance algorithms (Bryant et al., 2018; Klotz et al., 2019; Thurtle et al., 2018). Although most guidelines advocate selective use of MRI, the National Institute for Health and Care Excellence (NICE) guidelines from the United Kingdom mandate an MRI in all active surveillance patients. In addition, genomic testing may offer insight into the risk of occult adverse pathology and may offer insight into the likelihood of progression (Sanda et al., 2018a). In a recent study of men undergoing genomic testing and MRI, high scores with either were associated with biopsy upgrade. Clinical parameters such as biopsy core cancer density and higher PSA density (>0.15) place men at increased risk of being reclassified on subsequent biopsy (Bul et al., 2012, 2013; Welty et al., 2015), although African-American race (Leapman et al., 2016) and age do not.

An inclusive approach (Toronto) (Klotz et al., 2015), including all low-risk and selected intermediate risk (Gleason 7 or PSA >10) patients, and a restrictive approach (Hopkins) (Tosoian et al., 2015) offering surveillance only to patients who fulfilled the Epstein criteria (Gleason 6 with no more than 2 positive cores, no core more than 50% involved, and PSA density <0.15) had been studied as active surveillance protocols (Table 153.2). The actuarial 15-year prostate cancer mortality rate is 5.7% in the inclusive group and a prostate cancer mortality rate of 0.6% in the restrictive (Klotz et al., 2015). Most of the metastatic cases were Gleason score 7 at initial diagnosis (Klotz et al., 2015). There is an emerging consensus that the appropriate strategy lies between these two extremes.

TABLE 153.2

Selection Criteria for Active Surveillance

	CLINICAL STAGE	PSA LEVEL	GLEASON SCORE ON BIOPSY	PSA DENSITY	NUMBER OF POSITIVE BIOPSY CORES
University of Toronto (Schroder et al., 2014)	T1c/T2a	≤10–15 ng/mL	≤ 3+3=6	Not included	Not included
Multicenter European study (PIRAS) (Tsodikov et al., 2018)	T1c/T2a	≤10 ng/mL	≤ 3+3=6	≤ 0.2 ng/mL/cm (Wilt et al., 2012)	2
Johns Hopkins (Wilt et al., 2012)	T1c	Not included	≤ 3+3=6	≤ 0.15 ng/mL/cm (Wilt et al., 2012)	2
Canary Collaboration	T1/T2	Any	≤ 7	Any	Any

The appropriate method of surveillance remains controversial (Table 153.3). Traditionally, serial annual biopsy has allowed detection of occult high-grade disease and disease progression, although it is difficult to distinguish between the two. In general, a confirmatory biopsy, to be conducted within 6 to 12 months after diagnosis, is advocated by most protocols, but the frequency of subsequent biopsy is highly variable. A number of modeling evaluations have demonstrated that reduced sampling frequency may only slightly delay detection of disease progression while greatly reducing biopsy frequency (Inoue et al., 2018). One such protocol is that of the Prostate Cancer Research International Active Surveillance (PRIAS) program (van den Bergh et al., 2007), which is being increasingly used, particularly in Europe. Instead of annual pathological surveillance, patients undergo periodic PSA testing with less frequent biopsies. In these monitoring programs, PSA doubling time (PSADT) is used to determine the need for biopsy or intervention.

Death in men on active surveillance occurs most commonly from cardiovascular disease and rarely occurs from prostate cancer. In a mature cohort from Toronto (Klotz et al., 2015), with a median follow-up of 9 years, the relative risk for non–prostate-cancer death was 10 times that for prostate cancer mortality. Overall, 15% of men died by 15 years of follow-up, with 1.5% dying from prostate cancer and 2.8% developing metastasis. The likelihood of treatment by 5, 10, and 15 years was 25%, 36%, and 45%, respectively. In the Johns Hopkins series, with more strictly applied criteria, the rate of treatment at 10 and 15 years was 50% and 57%, respectively, with only 26% and 31%, respectively, demonstrating grade progression (Klotz et al., 2015). The benefit of implementing therapy in men with PSA progression only is not clear. **As such, among men considering surveillance, outcomes support safety, but the high rate of treatment suggests a critical need for adherence to follow-up.**

Decision Two: Partial Gland versus Whole Gland Treatment

In men deemed to be in need of treatment, or choosing treatment, the next stepwise decision, in those programs offering focal therapy, is between conventional whole gland/radical therapy and partial gland treatment, typically through thermal ablation. Criteria for selection of men for focal ablation are controversial and vary widely according to institution but typically include demonstration of unifocal, or limited focality, cancer in which imaging and biopsy demonstrate spatial concordance. **In those men, careful counseling regarding risks and benefits is required, with a clear understanding regarding the investigational nature of the approach.** Men must understand the absence of long-term clinical follow-up, the potential need for re-treatment, and the risk of worsened treatment outcomes if conventional therapy is eventually employed as a salvage option. In an ideal setting, partial gland ablation or focal therapy should be considered within a clinical trial setting.

In general, there is little consensus regarding the appropriate selection criteria for focal ablation, as many groups select men on the basis of transperineal mapping template biopsies and others use imaging. Although there is general consensus that high-risk patients should not be treated with focal ablation, given the absence of long-term locoregional control estimates, there is not clear consensus on whether low-risk disease, typically suitable for surveillance, is appropriate for focal ablation (Donaldson et al., 2015; Tay et al., 2017). Some groups have advocated selection of indolent disease for treatment (Tay et al., 2017), whereas most have felt that such treatment would be best applied to men with intermediate risk, limited focality disease (Donaldson et al., 2015; van den Bos et al., 2014). In a recent joint workshop of the Food and Drug Administration, the Society of Urologic Oncology, and the American Urological Association, clinical trial design, optimal end points, and candidate selection were discussed, demonstrating the growing interest in the treatment paradigm (Jarow et al., 2016).

In a study of 1490 men who underwent radical prostatectomy between 2000 and 2007, Tareen et al. (2009) demonstrated that 27.3% of men found to have unilateral disease on systematic biopsy had unilateral disease on final pathology. Clinical parameters demonstrating low-risk disease were unable to improve the prediction of unilateral disease. Others have demonstrated that the use of transperineal mapping template biopsy may improve the demonstration of multifocality, but as of yet the optimal template is not agreed upon (Singh et al., 2014). More recently, MRI-targeted biopsies have been suggested to improve the selection of men suitable for focal ablation, accepting that additional foci of indolent prostate cancer may be untreated (Nassiri et al., 2018).

The premise of focal therapy is that the index lesion, or dominant tumor, remains the primary origin of metastasis and potential lethality (Ahmed, 2009; Liu et al., 2009). Although proper methods of defining the index lesion remain unclear, it is generally considered by most to be the largest tumor focus with the highest Gleason score, most likely seen on MRI. The rationale for focal therapy remains untested in long-term follow-up but has led many investigators and clinicians to expand inclusion criteria for focal therapy to include men with low-grade secondary and tertiary sites of disease to be knowingly left untreated at time of index lesion ablation (Ahmed et al., 2015; Bott et al., 2010). Because the goal of focal therapy is primarily in destroying the index lesion, men enlisting for a focal ablative approach should realize that there is a high likelihood or residual cancer foci, whether recognized or not recognized by the baseline biopsy. The long-term efficacy of such approaches, along with the eventual impact upon survival, is unknown.

Decision Three: Surgery vs. Radiation versus Whole-Gland Ablation

If men require or desire whole-gland therapy, the next stepwise decision is between surgery, radiation, and whole-gland ablation. Although whole-gland ablation exists as an option, in many regards, consideration of its use is similar to that of focal ablative treatments. There is a paucity of long-term follow-up data, re-treatment is often required, and, when needed, salvage surgery is complicated by periprostatic scarring and fibrosis. The primary attraction of whole-gland ablation is the potential to preserve sexual and urinary function. Although whole-gland cryoablation almost always results in erectile dysfunction, preservation of function with whole-gland high-intensity focused ultrasound (HIFU) is more common but may vary with the aggressiveness and oncologic efficacy of the procedure. In addition, the need for re-treatment is 29% to 38% (Crouzet et al., 2010, 2014; Dickinson et al., 2016) with an increased rate of erectile dysfunction and stricture after a second treatment. As such, men considering whole-gland ablation by HIFU should be counseled with regard to the paucity of long-term outcomes and the potential need for re-treatment.

In general, the majority of decision making in whole gland therapy is between surgery and radiation. In counseling men regarding this most difficult decision, full assessment of patient longevity, baseline function, and goals of treatment is warranted. Although the goal of surveillance and investigational focal therapy is preservation of function, men seeking radical therapy are often primarily concerned with durable cancer control. Assessment of the cancer risk using one of several risk models allows an informed discussion of treatment efficacy and potential need for secondary treatments or multimodal approaches.

Much of the counseling relates to relative efficacy, but more often patients are concerned with relative risks and toxicities. Although a number of forms of radiation exist, the general side effect profiles are comparable, and comparisons between surgery and radiation can be made in general. Although there is a general belief that comparative data have demonstrated relatively equivalent oncologic outcomes between surgery and radiation at 10 years of follow-up, physician recommendations regarding surgery and radiation are often rooted in perceptions of patient longevity, disease risk, and secondary benefits and risks of treatment related to urinary and sexual quality of life. **In general, the decision between surgery and radiation, for most men with localized prostate cancer, is dependent upon patient perception and preference, and a decision**

regarding which anticipated side effects seem most tolerable to the individual.

Although an extensive discussion of the outcomes of prostatectomy and radiation is beyond the scope of this chapter and is covered elsewhere in the text, several points are noteworthy within the context of patient counseling and decision making. When men elect to undergo whole-gland therapy, realistic expectations regarding early outcomes must be provided before the treatment. Among men undergoing radical prostatectomy, early urinary and sexual toxicity is the norm, and patients should be mentally prepared to suffer incontinence and impotence in the early postoperative period to avoid decisional regret and frustration (Schroeck et al., 2008, 2012). Establishing a realistic time line and probability for recovery, along with a therapeutic plan, allows patients to tolerate recovery better. It is desirable that surgeons provide such outcome data, and expected recovery rates, based upon their own experience; outcomes are shown to be highly surgeon dependent.

In deciding between surgery and radiation, baseline urinary and sexual function should be carefully considered as outlined earlier. Men with significant baseline obstructive and irritative symptoms may benefit from surgery despite the early deterioration in urinary quality of life. Although randomized studies suggest relative equivalence of outcomes at 10 years (Hamdy et al., 2016), there are limited data regarding 15 to 20 years of follow-up, and as such, younger patients should be counseled regarding outcomes within the context of their estimated longevity.

When choosing radiation therapy, men may avoid the noted short-term urinary and sexual functional side effects, but counseling should focus on the long-term risks because most studies show incremental decline in urinary and sexual function, greater than the matched general population, with each year of follow-up (Barocas et al., 2017; Resnick et al., 2013; Tyson et al., 2018). The risk of delayed secondary malignancies is perhaps more controversial, but several studies support an increased risk of rectal and bladder malignancy at 15 to 20 years after external beam radiation (Nieder et al., 2008; Rombouts et al., 2018; Zhu et al., 2018). If intermediate or high risk, the best evidence often supports use of concomitant androgen deprivation therapy, and, as such, the early toxicity after radiation may be primarily driven by this. Despite the long-term risks, many men opt for radiation because of the clearly better early urinary and sexual outcomes as compared with surgery. Young men should be cautioned regarding the long-term risks as they relate to recurrence and toxicity.

Decision Four: Type of Treatment Delivery

Once a decision regarding a type of whole-gland therapy is made, further stepwise decisions relate to the available options for delivery of that modality. A specialist highly experienced in the delivery of that particular modality generally is best suited to conduct such discussions. In the case of surgery decisions between robotic-assisted laparoscopic and robotic approaches are generally related to the individual surgeon's experience and comfort level. Radiation has a multitude of options for treatment delivery, including external beam radiotherapy using intensity-modulated, image-guided, and/or three-dimensional conformal techniques; interstitial radiation using permanent seed implants or high dose rate temporary insertion; stereotactic body radiotherapy; and proton therapy. Radiation can be delivered in combinations, with conventional or hypofractionated treatment schemes. There has been growing concern that counseling regarding individual treatment options is often biased by financial incentives and physician biases (Bekelman et al., 2013).

Conclusion

The active management of prostate cancer is a complex process rooted in careful evaluation of the cancer and the host. The relative risk of cancer progression, metastasis, and cancer-specific mortality over time must be framed within the context of competing risks for mortality and the patient's expected longevity. Cancer risk can be assessed by a growing number of tools including biopsy pathology, image-based staging, MRI, and genomic markers. Available data can be combined for prognostic predictions through one of a multitude of validated nomograms or risk assessment scores. Patient longevity can be predicted on the basis of age, comorbidities, and standardized scales of longevity assessment. Collectively, these data can be integrated to provide the patient with available, appropriate management options, and an individualized decision-making framework. Because the available treatments are many and the goals of differing management strategies are often divergent, a stepwise or decision-tree patient counseling approach can simplify patient counseling and offer more informed decisions, thereby reducing decisional regret.

Active Surveillance of Prostate Cancer

Laurence Klotz MD, FRCSC

The past decade has witnessed a dramatic change in the approach to men with favorable-risk prostate cancer (Klotz, 2017). Ten years ago, more than 90% of men in the United States, Canada, and Europe diagnosed with this condition were treated radically, with either surgery or radiation. Today, in some regions more than 90% are treated expectantly, using an approach termed *active surveillance*. Most centers report at least 50% of low-risk patients being managed this way. This profound change had many drivers, including concerns about the risk for overtreatment expressed by many constituencies, particularly the U.S. Preventive Services Task Force (USPSTF); data on the favorable molecular genetics of Gleason pattern 3 cancer; long-term outcome data from prospective cohorts of patients managed with surveillance; enhanced ability to identify those patients at risk using modern imaging and molecular biomarkers; robust modeling studies confirming the benefit of active surveillance compared with definitive therapy; and, above all, patient acceptance and enthusiasm for a less aggressive approach. This chapter is a comprehensive review of the background, rationale, biologic basis, outcome, and technique of active surveillance.

The Overdiagnosis and Overtreatment Problem

In modern medical practice, the advent of sensitive diagnostic testing has resulted in the overdiagnosis of many disease states. Cancer overdiagnosis and overtreatment is a problem in many organs. It is estimated that the “overdiagnosis” rates for prostate, thyroid, and breast cancer if the entire reservoir of disease were being detected would be 87% to 94%, 99.7% to 99.9%, and 43% to 90%, respectively (Welch and Black, 2010). These estimates reflect the high prevalence of microfocal disease in the healthy population (30% to 70% for prostate, 36% to 100% for thyroid, and 7% to 39% for breast cancer).

Because of the high incidence of latent prostate cancer in aging men, the widespread availability of the prostate-specific antigen (PSA) test, and the long-term effects of definitive therapy, overdiagnosis and overtreatment pose significant risks in the management of prostate cancer.

Screening for prostate cancer with PSA is widely prevalent in North America and Europe. Compared with relying on clinical diagnosis in men presenting with symptoms or signs, it results in the identification of potentially lethal prostate cancer at a much more curable stage. The widespread use of PSA has been associated with significant decreases in prostate cancer mortality (Jemal et al., 2010). The cost, however, has been a high rate of diagnosis—and treatment—of prostate cancer, many cases of which are likely clinically insignificant.

The USPSTF recommendations on the use of PSA for screening, published in 2012, assign it to level D, mainly based on concerns about overdiagnosis and overtreatment (USPSTF, 2018). In 2018, after a great deal of debate, the recommendation regarding PSA screening was modified to a level C (neutral) recommendation, largely due to the uptake of active surveillance, resulting in a reduction in overtreatment (U.S. Preventive Services Task Force et al., 2018).

A solution to the problem of overtreatment is to identify patients at low risk for disease progression and manage them conservatively. This strategy is based on the concept that treatment is best individualized, and the timing and aggressiveness of treatment should reflect disease and patient characteristics.

Conservative management of localized prostate cancer is guided by two different practical strategies, either “active surveillance” or “watchful waiting.” Active surveillance is the approach taken in men whose age and general health make them candidates for radical local therapy if needed. These patients are regularly monitored over time, and if they are reclassified as being at higher risk for disease progression, then they are offered definitive therapy. In contrast, watchful waiting consists of minimal follow-up with palliative therapy of advanced disease in the unlikely event that it becomes clinically manifested; definitive local therapy is not a therapeutic option because of age and comorbidity. Many patients are initially managed with active surveillance and converted to watchful waiting once their average life expectancy is calculated to be less than 5 to 8 years (typically around 80 years of age, or earlier if they have significant comorbidity).

Active surveillance offers the benefit of avoiding the significant side effects of radical local therapy for those with indolent, stable, or regressive disease, with the option of definitive therapy for those patients who are reclassified over time as having higher risk for disease progression, usually based on finding higher-grade disease than on the initial biopsy.

This approach rests on the presumptions that the lead time from diagnosis to clinical progression for low-risk disease is usually long (Draisma et al., 2009) and that the cancer can be treated within the window of curability at the first signs of higher-risk disease. The distinction between surveillance and watchful waiting is important. Studies reporting on oncologic and quality-of-life (QoL) outcomes from older randomized trials (Bill-Axelson et al., 2011) or population-based registries (Albertsen et al., 2005b), where patients were managed with observation (i.e., watchful waiting), should not be considered representative of outcomes expected with contemporary active surveillance, where a significant proportion of men are eventually reclassified to higher risk and offered definitive therapy.

The Natural History of Prostate Cancer

Autopsy studies have demonstrated that the likelihood of harboring microfocal prostate cancer is approximately a man's age as a percentage: 30% of men in their thirties, 50% in their fifties, and 80% or more in men older than 80 years of age (Sakr et al., 1994). PSA testing followed by systematic biopsies of the prostate for those whose level is elevated results in diagnosing prostate cancer in 15% to 20% of men, depending on the threshold for biopsy. In contrast, the lifetime risk for death from prostate cancer in North America is 3%. Thus the ratio of harboring prostate cancer to death is about 20 : 1, and the ratio of diagnosis to death is about 6 : 1. Obviously, therefore, many men diagnosed with localized prostate cancer are not destined to die of the disease. Most of these men would have never had symptoms or been diagnosed without PSA testing. These are considered “clinically insignificant” cancers.

The indications for biopsy determine the likelihood of diagnosis of clinically insignificant cancer. Recognizing that 50% to 60% of men in the biopsy age group harbor microfocal prostate cancer, it is apparent that the lower the PSA threshold for biopsy, the more cores that are taken at each biopsy, and the more biopsy sessions a patient undergoes (despite an initial negative biopsy), the more likely clinically insignificant cancer will be discovered. The benefits and pitfalls of screening are thoroughly addressed elsewhere in this book.

Clinical parameters allow one to identify those men at low risk for disease progression. By far, the most powerful predictor of disease aggressivity is the Gleason grade grouping (until recently known as the Gleason score). For the purposes of this chapter, low-grade cancer refers to Gleason grade group 1, or a Gleason score of 6 (3+3). Intermediate-grade cancer is Gleason grade group 2 (Gleason 3+4) and group 4 (Gleason 4+3). High-risk cancer is Gleason grade group 4 (Gleason 8) and group 5 (Gleason 9 and 10).

The basic concept of active surveillance is to manage patients with low-grade prostate cancer conservatively, reserving treatment for those who are upgraded over time. Selected patients with intermediate-grade cancer are also candidates. The outcome of this approach and the principles of management are described later in this chapter.

Molecular Genetics of Gleason Pattern 3 Versus

Patterns 4 and 5

Molecular and genetic analyses have shown that the hallmarks of cancer differ profoundly between the two most common patterns of disease, Gleason 3 and Gleason 4. These hallmarks are a useful structure for determining the degree to which low-grade prostate cancer (Gleason pattern 3) “looks” like a true malignancy (Draisma et al., 2009).

The “hallmarks” of cancer include six biological capabilities acquired during the development of human tumors such as sustained proliferative signaling, activation of local invasion and metastasis, induction of angiogenesis, evasion of growth suppressors, resistance to cell death, and unlimited replicative potential (Hanahan and Weinberg, 2011). Analysis of alterations of these molecular pathways by gene amplification, mutation, or deletion has shown that most Gleason pattern 3 cells have relatively normal molecular features, and Gleason pattern 4 and 5 cells are altered (Ahmed et al., 2012).

This is particularly true of genes regulating key oncogenic pathways (Table 154.1). Genes involved in proliferation, including *AkT* and *HER2*, are expressed normally in Gleason pattern 3 and abnormally expressed in Gleason 4 (Ross et al., 2011; Skacel et al., 2001). Genes involved in cellular invasion and metastasis (True et al., 2006) and genes regulating cell cycle transition are not overexpressed in Gleason pattern 3, but are overexpressed in Gleason 4 (Padar et al., 2003; Susaki and Nakayama, 2007). Genes associated with resistance to apoptosis (Fleischman et al., 2012), angiogenesis, and the development of other pro-angiogenic factors (Erbersdobler et al., 2010; West et al., 2001), and genes involved in regulating cellular metabolism (Georgescu et al., 2016), including the reverse Warburg effect, tend to be abnormally expressed in Gleason pattern 4 but not in Gleason 3.

TABLE 154.1

Gleason 3 vs 4 and Hallmarks of Cancer

PATHWAY	**GLEASON 3**	**GLEASON 4**
EGF, EGFR (Ross et al., 2011)	No	Overexpressed
AKT, MAP2 kinase (Ross et al., 2011)	No	Aberrant
HER2neu (Skacel et al., 2001)	No	Amplified
Markers of tissue invasion and metastasis (Ross et al., 2011; True et al., 2006)	Normal	Overexpressed

Insensitivity to growth inhibitory signals (e.g., cyclin D2) (Susaki and Nakayama, 2007; Padar et al., 2003)	Expressed	Absent
Resisting Apoptosis, BCL2 (Fleischmann et al., 2012)	Negative	Strong expression
VEGF, Microvessel density, other pro-angiogenic factors (West et al., 2001; Erbersdobler et al., 2010)	Low expression	Increased
Metabolic pathways (reverse Warburg) (Georgescu et al., 2016)	Absent	Present
Absence of senescence, TMPRSS2-ERG (Bismar et al., 2012; Wang et al., 2006)	ERG normal	Increased
PTEN (Trock et al., 2016)	Present in 90%	Deleted in 70% to 90%
Clinical evidence of metastasis/prostate cancer mortality after surgical grading (Hubbard et al., 2016; Ross et al., 2012)	Absent	Present

Translocations of *TMPRSS2-ERG* (Bismar et al., 2012; Furusato et al., 2008; Wang et al., 2006) and *pTEN* deletions (Trock et al., 2016) are common in Gleason pattern 4, and are absent or only occasionally expressed in Gleason 3 (see Table 154.1). The implication is that most Gleason pattern 3 cells behave in a “benign” fashion, whereas higher-grade patterns harbor the ability to invade and metastasize.

It is remarkable how well the Gleason scoring system disaggregates prostate cancer between genetically normal and abnormal cells. According to those who knew him personally, Don Gleason himself thought that Gleason pattern 3 or less should not be called cancer.

The differences in gene expression are quantitative and qualitative. The mutational load of Gleason pattern 3 is dramatically less than for higher-grade cancer, but it is not zero. For example, about 10% of Gleason pattern 3 cancers have a *PTEN* deletion. This is found much more commonly in Gleason pattern 3 cells in men with coexistent Gleason pattern 4 (i.e., Gleason score 7 cancers) (Trock et al., 2016). This may indicate that a field defect is present or that Gleason 3 cells harboring the *PTEN* deletion rapidly dedifferentiate to a higher Gleason pattern. An alternative explanation is that the deleterious genetic alterations present in the higher-grade cancers are transferred by exosomes into the lower-grade cancers (Zomer and van Rheenen, 2016). As an isolated abnormality, *PTEN* deletion does not seem to confer a metastatic potential. Recent studies suggest that *MYC* amplification in conjunction with *PTEN* deletion induces genomic instability and metastatic prostate cancer, and both events may be required to confer a metastatic phenotype (Hubbard et al., 2016).

The favorable molecular profile of Gleason pattern 3 is associated, not surprisingly, with benign natural history. There is compelling data that Gleason pattern 6 cancer has no metastatic potential. One study of 14,000 men with pathologically confirmed Gleason pattern 6 cancer identified only 22 cases with lymph node metastases (Ross et al., 2012). All 22 men had higher-grade cancer on re-examination of the tissue. Thus, the rate of lymph node metastases in men who had the benefit of surgical pathologic confirmation that their prostate contained no higher-grade cancer was zero. Another study of 12,000 men treated with radical prostatectomy whose specimen had only Gleason 6 cancer found the prostate cancer mortality was 0.2% at 20 years (Eggener et al., 2011). The few cases who had metastases had evidence of higher-grade cancer on re-review of their original histology. It is therefore reasonable to conclude that the metastatic potential of Gleason pattern 3 cancer is, for all intents and purposes, zero.

Although coexistent higher-grade cancer is common, spontaneous-grade progression (from Gleason pattern 3 to pattern 4 or 5) is uncommon. This has been modeled by several groups; the estimate is that 1% to 2% of patients per year will undergo grade progression. In most cases, this occurs in high-volume Gleason 6 cancers (Inoue et al., 2014). The implications are that patients on active surveillance must be followed long term, and 10% to 20% will undergo true, biological grade progression after 10 years. Although evidence of grade progression should be sought as long as the patient is on surveillance, it would not necessarily warrant intervention. For example, progression to Gleason 3+4 after 10 to 15 years of surveillance in a man diagnosed at 65 years of age who is now 80 would not necessarily pose a threat to his life.

All series including men with low-risk prostate cancer managed conservatively report occasional cases of metastatic disease. In most cases, this is because the assessment of grade has relied on biopsy only. The adverse outcome in these cases reflected the presence of occult higher-grade cancer present in the prostate at the time of diagnosis that was missed on the diagnostic biopsy. This situation exists in about 30% of men diagnosed on the basis of a 10- to 12-core systematic biopsy. In 85% of these cases, the upgraded cancer is Gleason 3+4 (Porten et al., 2011); however, 10% of the undergraded 30% harbor Gleason 4+3, and 5% harbor Gleason 8 or higher cancer. These occult high-grade cancers are almost certainly responsible for the few patients who progress to metastatic disease despite being diagnosed with low-grade cancer.

Another explanation for the metastasis rate seen in earlier watchful waiting series was the change in Gleason grading system introduced in 2005. Many cancers previously graded as Gleason score 6 before 2005 are now graded as Gleason 7 (Epstein et al., 2017). This upgrading resulted in a typical stage migration phenomenon, resulting in an improvement in cancer-specific survival estimated at 26% (Albertsen et al., 2005a).

Key Points

- Microfocal Gleason pattern 3 occurs in most men with age, in all races and regions of the world.
- The mutational burden of Gleason pattern 3 cancer is very favorable and dramatically different from higher-grade cancer. Most oncogenic pathways characterized by specific genetic alterations are normal in Gleason pattern 3 and aberrant (e.g., deleted/amplified/mutated/overexpressed) in Gleason patterns 4 and 5.
- Gleason pattern 6 cancer (grade group 1) has no metastatic potential.
- Cancer deaths reported in men with low-risk cancer managed conservatively are thought to be caused by the coexistence of higher-grade cancer missed on the diagnostic biopsy.

Natural History

The natural history of untreated prostate cancer has been determined by both observational studies (Albertsen et al., 2005b) and several randomized studies comparing radical intervention to expectant management. These studies must be evaluated in the context of the diagnostic pathway in place at the time; in particular, studies of PSA-screened patients will reflect lead time bias of 5 to 10 years with respect to disease progression and survival compared with a nonscreened population. Most of these studies did not utilize an “active surveillance” approach in the nontreatment arm, whereby patients had close monitoring, serial biopsy, and so on. As mentioned earlier, the progression and mortality rates reflect the predictable presence of occult higher-grade cancer in 25% to 30% of the patients.

The study with the longest follow-up of conservative management followed 223 men in Sweden over 32 years (Popiolek et al., 2013). The majority were older than 70 years of age at diagnosis, and 99% of the cohort died. In this study, 64% remained untreated, and none of the untreated patients developed metastatic progression; 14% with Gleason 6 disease on biopsy developed metastatic disease. This study, and others, concluded that the rate of progression is stable for many years and does not increase significantly over time. The Swedish study did report an increase in prostate cancer mortality after 15 years. However, this increase appears to be an artifact related to the small numbers of men surviving beyond 15 years. In addition, these patients did not have the benefit of close monitoring and delayed intervention for risk reclassification.

There have been three large randomized trials that compared the outcome of expectant management (usually watchful waiting) to radical prostatectomy. The control arms of these studies provide insight into the natural history of untreated prostate cancer. The three studies are the Scandinavian Prostate Cancer Group Study Number 4 (SPCG-4) in Scandinavia (Bill-Axelson et al., 2014), the Prostate Cancer Intervention versus Observation Trial (PIVOT) in the United States (Wilt et al., 2017), and the Prostate Testing for Cancer and Treatment (ProtecT) study in the United Kingdom (Hamdy et al., 2016). Each of these is a critically important study.

The SPCG-4 randomized 695 men with a mean age of 65 years to radical prostatectomy versus observation (Bill-Axelson et al., 2014). Only 5% were diagnosed based on PSA testing; 75% had a palpable nodule; and the median PSA was 13. Thus this was largely an intermediate- to high-risk cohort. In this study, 21% of men in the observation arm died of prostate cancer. Among the low-risk observation cohort, defined as PSA less than 10 ng/mL, and Gleason score ≤6, the prostate cancer mortality was 11%. Revealingly, 7 men in the prostatectomy arm with low-risk disease on biopsy went on to die of prostate cancer; all of these were upgraded at radical prostatectomy. Although surgery resulted in a significant improvement in survival overall, the benefit was confined to men 65 years of age or younger. Men older than 65 years of age had no benefit from surgery compared with no treatment. Recognizing the important differences between this group and a contemporary active surveillance cohort (modern Gleason grading, PSA-based diagnosis, close monitoring with serial biopsy, and/or imaging), it is reassuring that the long-term prostate cancer mortality in the low-risk cohort was modest. Further, the data emphasizes the value of conservative management in older patients, including those with higher-risk disease. Importantly, stratification analysis showed that the benefit of surgery was confined to the GG3 and higher population; there was no benefit in

GG1 or GG2, emphasizing the potential benefit of surveillance in the favorable intermediate risk group (Bill-Axelson et al., 2018).

The PIVOT (Wilt et al., 2017), carried out in the VA hospitals in the United States, similarly randomized 731 men between surgery or observation. This was a somewhat more favorable cohort than the SPCG-4 group. The median PSA was 7.8, and most were diagnosed with PSA testing. There was little difference in prostate cancer mortality between the two arms. The modest difference that was seen was mostly in the intermediate-risk group. Prostate cancer mortality occurred in only 2.7% of the low-risk observation group (vs. 11% and 17% in the intermediate- and high-risk groups, respectively). The similarity in disease-specific mortality rate between the low-risk group in the SPCG-4 (11%) and the intermediate-risk group in the PIVOT (11%) likely reflects the stage-migration effects of PSA testing, the change in Gleason grading in 2005, and lead time effects.

The long-awaited ProtecT trial reported recently (Hamdy et al., 2016). This was a randomized trial comparing active monitoring, radical prostatectomy, and external-beam radiotherapy. The primary end point was prostate cancer mortality at 10 years. In this study, 1643 men identified in a screening trial agreed to undergo randomization among the three arms. There were 17 prostate cancer–specific deaths overall, and there was no difference among the three groups in disease-specific mortality or overall survival. The active monitoring group had more metastases (6.3 events per 1000 person-years versus 2.4 with surgery and 3 with radiation).

A key fact in this important trial is that patients with intermediate- and high-risk cancer were included in the active monitoring arm. At diagnosis, 23% of the patients had intermediate- or high-grade cancer on biopsy. Given the low rate of metastasis, a higher rate of progression in the 23% of patients in the intermediate- and high-risk groups is more than sufficient to explain the increase in metastasis rate in the expectant management group. That 77% of the cohort had low-risk disease is also a likely explanation for the failure to see a difference in mortality among any of the arms, as the study was therefore underpowered in terms of the number of clinically significant cancers to show a difference at 10 years.

Active monitoring in the ProtecT trial did not mean active surveillance as described earlier. Biopsies were not performed on an established schedule, and criteria for intervention were not clearly described. This may also have contributed to the higher metastasis rate in the expectant management arm.

Importantly, QoL on the active monitoring arm was the same or better in every domain measured (Donovan et al., 2016).

Outcome of Active Surveillance

Ten prospective phase II active surveillance studies have reported, comprising about 10,000 men in total (Bul et al., 2013; Dall'Era et al., 2008; Khatami et al., 2007; Klotz et al., 2015; Kovac et al., 2017; Patel et al., 2004; Roemeling et al., 2007; Selvadurai et al., 2013; Soloway et al., 2008; Tosoian et al., 2015). The largest and most mature studies are summarized in Table 154.2. Several of these studies include hundreds of patients followed for more than 15 years.

TABLE 154.2

Results of Mature Active Surveillance Cohorts

STUDY	*N*	MEDIAN FOLLOW-UP YEARS	FREEDOM FROM TREATMENT	bNED AFTER DEFERRED TREATMENT	PROSTATE CANCER MORTALITY %	OTH CAU MOR %
University of Toronto (Klotz et al., 2015)	993	8.5	70% at 5 years	5-years bNED: 47%	5% at 15 years (actuarial) 1.5% (actual)	10 ye

(Selvadurai et al., 2013)				years		

bNED, no evidence of biochemical disease.

Consistent with the data from randomized trials described earlier, prostate cancer mortality is rare in men with low-risk disease managed with active surveillance. The most common cause of death in these patients is cardiovascular disease. In the most mature cohort (Klotz et al., 2015) with a median follow-up of 9 years, the relative risk for non–prostate-cancer death was 10 times that for prostate cancer mortality.

Active surveillance inclusion criteria have varied among groups. Two groups, Toronto (Klotz et al., 2015) and Hopkins (Tosoian et al., 2015), represent the two extremes of an inclusive and restrictive approach, respectively. Both groups have reported 15-year outcomes. A comparison between the outcomes in these groups allows one to define the relationship between patient selection and outcome.

The Toronto group took an inclusive approach, including all patients with Gleason 6 cancer, and selected intermediate-risk patients (Gleason 7 or PSA >10) (Selvadurai et al., 2013). The actuarial 15-year prostate cancer mortality rate was 5%. The hazard ratio (HR) for metastasis at 15 years was 3.75 times greater for intermediate-risk patients than for low-risk patients. PSA greater than 10 had very little correlation with the likelihood of eventual metastasis.

However, the patients with Gleason 7 at baseline were particularly at risk; these patients had a 20% or greater metastasis rate at 15 years (American Urological Association [AUA], 2017; Chen et al., 2016). This relatively high rate of metastasis occurred despite the fact that all of these patients were deemed to “progress” (based on substantial risk in PSA, or grade or volume progression) and were treated radically before they were found to have metastatic disease.

In contrast, the Hopkins group took a restrictive approach, offering surveillance only to patients who fulfilled the Epstein criteria (Gleason 6 with no more than two positive cores, no core >50% involved, and PSA density <0.15). The benefit was a prostate cancer mortality rate of 0.5% at 15 years. The cost was that only about 20% of newly diagnosed patients were eligible (vs. 50% in the Toronto cohort). Although the long-term mortality rate is clearly influenced by the inclusion criteria for surveillance, the intervention rate has been remarkably consistent. The rate of intervention is consistently around 25% at 5 years (Komisarenko et al., 2016).

In the beginning of the “active surveillance era,” the optimal strategy for follow up and intervention was unclear. The long-term surveillance studies have provided clarity. There is an emerging consensus that the appropriate strategy lies between the two extremes described earlier. Most Gleason 6 patients are appropriately managed with surveillance (i.e., not just those fulfilling Epstein criteria), and, in contrast, active surveillance should be offered selectively and cautiously to Gleason 7 patients.

All of the mature surveillance cohorts reflect the experience before the incorporation of magnetic resonance imaging (MRI) and molecular biomarkers. It is very likely that the incorporation of these augmented strategies will broaden the indications for surveillance while further reducing the already low rate of metastasis.

Key Points: Outcome of Conservative Management

- Three randomized trials comparing radical intervention to various versions of conservative management have shown little or no benefit to intervention in the low-risk group.
- Ten prospective active surveillance series have confirmed a very low rate of metastasis and prostate cancer mortality with an initial conservative approach. The disease-specific mortality varies between 0.5% and 5% at 15 years, depending on eligibility criteria.
- Approximately 25% of patients are reclassified to higher risk and managed with definitive therapy at 5 years. This figure is similar among all cohorts.
- These data reflect the pre-MRI era of surveillance. Incorporating MRI and biomarkers is likely to improve the already favorable outcome substantially by providing earlier identification of the aggressive cancers.

Patient Selection

Most men with grade group 1 (Gleason 3+3=6) prostate cancer should be managed with active surveillance. This view is now reflected in guidelines from many groups, including Cancer Care Ontario (Morash et al., 2015), the AUA (AUA, 2017); ASCO (Chen et al., 2016), and NICE (2017) (Table 154.3).

TABLE 154.3

Summary of Contemporary Active Surveillance Guidelines

5ARIs, 5α-reductase–specific antibodies; *AS,* active surveillance; *DRE,* digital rectal examination; *PSA,* prostate-specific antigen.

Currently, most guidelines make a distinction between very low risk (Epstein criteria, i.e., only one to two positive cores, no core with >50% involvement, and PSA density <0.15) and low risk (any grade group 1 with PSA <10). The distinction between low risk and very low risk does not reflect a difference in the metastatic potential of Gleason pattern 3 as a function of cancer volume. What it does reflect, rather, is the likelihood of coexistent occult higher-grade cancer, and (possibly) the risk for eventual grade progression. High-volume Gleason 6 cancer is associated with an increasing risk for coexistent higher-grade cancer. The higher volume manifests itself in a higher PSA density, increased number of systematic cores involved, and increased extent of core involvement. Several nomograms have been published that indicate the likelihood of coexistent higher-grade cancer based on these clinical and pathologic parameters (Jain et al., 2015; Mamawala et al., 2017). Thus a patient with high-volume Gleason 6 cancer is still a surveillance candidate, but requires closer scrutiny to exclude coexistent higher-grade disease, either with multiparametric magnetic resonance imaging (mpMRI) and targeted biopsy, repeat extended biopsy, and/or a tissue-based genetic assay.

Watchful Waiting

The conceptual basis for active surveillance is that patients are candidates for radical therapy based on age and comorbidity (usually meaning a life expectancy of 5 to 10 years or more), but do not require it because of the indolent nature of the disease.

Several studies have demonstrated that in the 5-year time frame, only patients with very aggressive, high-grade disease are at risk for cancer death (Albertsen et al., 2005b; Popiolek et al., 2013).

Therefore in elderly or comorbid patients, where the harm of radical therapy for localized disease is likely to outweigh the benefit, the approach of watchful waiting is more appropriate. This means monitoring patients only with infrequent PSA and clinical assessment, with no biopsies or imaging, and treatment only for symptomatic progression (or, rarely, for metastatic disease). The watchful waiting approach is often used for newly diagnosed elderly or comorbid patients with low- to intermediate-risk cancer. In addition, patients on long-term active surveillance are “switched” to watchful waiting when their life expectancy becomes less than 5 to 10 years. Determining when to make this switch is a judgment call that can be assisted by nomograms that predict life expectancy based on age and comorbidity.

A pitfall in following prostate cancer patients is the development of neuroendocrine dedifferentiation resulting in clinical progression without PSA progression. This is rare in the patient with an intact gonadal axis, but occasionally may be seen in the elderly male with unrecognized hypogonadism. Therefore PSA must be used as a guide and not relied on 100%, and testosterone should be assayed in those in whom hypogonadism is a possibility.

Hard rules for the timing of the switch to watchful waiting are unrealistic, reflecting the reality that some patients with a life expectancy of close to 10 years may still prefer definitive therapy if they are found to have significant disease. Patients may be motivated by concerns about “modus mortis” (manner of death), that is, the desire to avoid a prostate cancer death even if their risk is relatively modest. Further, our ability to predict survival based on age and comorbidity is inexact. Some patients live considerably longer than their median life expectancy. Patient preferences and tradeoffs play a role in this population.

Management of Men on Active Surveillance

Although safe for most men, there are two aspects of conservative management that warrant caution and scrutiny. The first and most common is misattribution of grade. As mentioned, about 30% of men found to have Gleason 6 (grade group 1) cancer on systematic biopsy are found to have higher-grade disease at radical prostatectomy (Epstein et al., 2012). Similarly, about the same proportion will be upgraded if subjected to annual biopsies over 10 years (Tosoian et al., 2013). Most are upgraded to GG2, and upgrading beyond GG3 is rare.

As mentioned, the presence of occult high-grade cancer (the “wolf in sheep's clothing”) can be predicted by a number of clinical factors. These include PSA density, PSA level, the free versus total ratio, the extent of disease on biopsy (number of cores and extent of core involvement), increasing age, and race. In addition, restricted diffusion on MRI is a powerful predictor of high-grade cancer.

The second phenomenon that puts patients at risk is true biologic grade progression, whereby Gleason pattern 3 progresses to pattern 4 or 5. This is much less common than the misattribution of grade based on systematic biopsies. Importantly, many of the cases in which patients have progressed to Gleason 3+4 will still have indolent disease. The proof of this is that, despite the known rate of undergrading, vagaries in pathology interpretation, and the rate of spontaneous grade progression, the mortality rate of “low-risk” men managed with surveillance is extremely low.

The experience with misattribution and undergrading described in the surveillance literature largely reflects the pre-MRI era. Increasingly, patients on surveillance have an MRI and targeted biopsy. The rate of undergrading is substantially less with targeted biopsy than with systematic biopsy (Ahmed et al., 2017; Radtke et al., 2016). It is reasonable to expect that, with the increasing use of MRI, this misattribution rate will decline substantially. This should have many positive benefits, including earlier identification of aggressive high-grade cancer; reassurance to patients with a negative MRI or targeted biopsy that their risk for harboring high-grade cancer is low; and a more accurate signal for intervention.

Other Risk Factors

Race

Racial differences in prostate cancer incidence and mortality are substantial, and these are relevant to the surveillance population. Black men appear to have an increased risk for harboring coexistent higher-grade cancer than Caucasians. Whether this represents patient selection or differential access to early detection is unclear (Iremashvili et al., 2012). One group reported an increased rate of definitive intervention and a higher rate of disease progression (Odom et al., 2014). The literature is inconsistent. A recent meta-analysis identified eleven studies on pathologic results of African-American men who would qualify for active surveillance (Gökce et al., 2017). In eight of these studies, African-American race was found to be associated with adverse pathologic outcomes such as positive surgical margins, upgrading, or upstaging. Three studies reported no significance in these parameters with respect to race.

Although they may have a higher risk for harboring higher-grade cancer, black men are unequivocally candidates for surveillance. With the increasing use of MRI to identify those harboring high-grade cancer, they should experience a level of safety comparable to Caucasians.

Family History

Although family history is relevant to an individual's risk for prostate cancer, in most cases it should not drive a decision toward radical treatment. There are several reasons for this. The advent of PSA screening resulted in a dramatic increase in prostate cancer diagnosis. Many of these cases were clinically insignificant. However, this may not have been recognized. The family members of an individual diagnosed with clinically insignificant prostate cancer only know that they now have a family history—and are thus more likely to be screened themselves, and in many cases also diagnosed with clinically insignificant disease. This phenomenon has resulted in “family history inflation.”

In most cases in which a family member was treated for localized prostate cancer, therefore, relatives diagnosed with low-grade disease are still surveillance candidates.

A history of metastatic disease at a young age (<60) in a first-degree relative is significant and may reflect a germline predisposition to prostate cancer. There is an increasing recognition that in such cases, screening for germline mutations, particularly in genes involved in DNA repair, should be performed in family members.

Germline mutations in DNA repair genes (*BRCA1* and *BRCA2*, and *ATM* in particular) confer an accelerated acquisition of mutations and an aggressive phenotype (Taylor et al., 2017). Recent studies that analyzed the genomes and methylomes of localized prostate cancer from *BRCA2* mutation carriers showed that these cancers had increased genomic instability and a mutational profile that resembled metastatic disease. In one study of surveillance in men with germ line DNA repair defects, the hazard ratio for any upgrading in men with BRCA2 mutations was 2.6, and for upgrading to ≥GG3 was 5.1. By 10 years, 80% of BRCA2 patients were upgraded. BRCA1 and ATM were also associated with increased risk, although not as great (Carter et al., 2019). This suggests that in men with *BRCA* mutations, definitive therapy should be considered, even if low-grade prostate cancer is present. The implication is that screening for DNA repair defects should be considered in many patients with prostate cancer, particularly when there is a family history of prostate, breast, or ovarian cancer. The role of genetic screening in this population is currently a matter of controversy.

Monitoring

Patients on surveillance should be managed with a combination of serial PSAs (usually every 6 months), digital rectal examination (annual), and MRI and/or prostate biopsy every 2 to 5 years after the initial confirmatory biopsy. The finding of Gleason score 7 or higher should, in most cases, prompt intervention. An increase in volume of Gleason 6 cancer alone should not prompt intervention; rather, it should prompt a search for higher-grade cancer using MRI or a molecular biomarker.

Magnetic Resonance Imaging

Multiparametric MRI incorporating diffusion-weighted imaging (DWI) is a sensitive and specific test for higher-grade prostate cancer. The diffusion of water through tissues correlates inversely with the Gleason score (Vargas et al., 2011). This reflects the fact that higher-grade prostate cancer has a smaller, more poorly designed lumen than lower-grade cancer, thus impairing diffusion of H_2O. Thus MRI including assessment of diffusion has the appeal of not identifying lower-grade cancer, while providing important information on the location, size, and severity of higher-grade cancer.

MpMRI clearly improves the accuracy of targeting significant cancer in men on surveillance compared with systematic biopsies. In a recent pooled review of 8 series comprising a total of 931 active surveillance candidates who underwent mpMRI before confirmatory biopsy, mpMRI was positive in 73% of patients (Schoots et al., 2015). A total of 32% of patients (297/931) were upgraded at confirmatory biopsy. Cancer upgrading occurred in 13% (121/931) on both systematic and targeted biopsies, in 11% (105/931) on systematic biopsy alone, and in 8% (71/931) on MRI-targeted biopsy alone.

The negative predictive value (NPV) of MRI for excluding clinically significant cancer ranges from 70% to 100% in various series. The NPV is in part a function of the underlying risk of upgrading. In men with a 30% chance of upgrading, the NPV is 88%; in men with a 60% chance (based on high PSA density and extensive disease on biopsy) the NPV is only 66% (Moldovan et al., 2017).

These data suggest that mpMRI is useful before confirmatory biopsy, but that systematic biopsies should be performed in addition to targeted biopsies. Performing mpMRI before confirmatory biopsy is now recommended by the NICE guidelines. In patients on active surveillance with a negative MRI, systematic biopsies can likely safely be deferred in very-low-risk patients. In those at higher risk for upgrading, systematic biopsies are still warranted.

Biomarkers

Prospective active surveillance cohorts now compose more than 10,000 patients, thousands of whom have been followed for longer than 10 years. Clinical parameters (PSA, PSA density, extent of disease on biopsy, race, T-stage) allow for risk stratification for coexistent higher-grade disease. Monitoring low-risk patients on surveillance is associated with a risk for clinical progression of 0.2% to 5% at 15 years. Therefore, the benefit to most patients of a biomarker to further stratify patients according to the risk for progression is modest.

However, selected patients, particularly those whose risk factors suggest they are at above average risk for higher-grade disease, may benefit from genomic testing. There are two potential benefits: (1) reassurance for patients with a favorable genomic risk score that conservative management is likely to be safe and (2) earlier identification of those at risk for disease progression on active surveillance who could benefit from treatment. Clinical studies have demonstrated a greater utilization of conservative management in those who have access to genomic testing.

Three genetic tissue assays have been approved to date by the U.S. Food and Drug Administration (FDA) for men with prostate cancer and are summarized as follows:

Genomic Classifier

This is a 22-marker genomic classifier (GC) based on RNA expression. GC had independent predictive value on multivariable analysis for predicting metastasis after prostatectomy, with an HR of 1.5 for each 10% increase in score (Klein et al., 2016), and these results were validated in two separate prostatectomy cohorts (Nguyen et al., 2017a, 2017b). A high score is associated with an increased risk for disease-specific mortality and progressive disease after salvage radiation. The Decipher biopsy test (Decipher Biosciences, San Diego, CA) can predict metastasis and disease-specific mortality from diagnostic biopsy specimens of primarily intermediate- and high-risk men treated with first-line radiotherapy or radical prostatectomy (Nguyen et al., 2017a). The Decipher test also is an accurate predictor for adverse pathology in the favorable intermediate risk population (Herlemann et al., 2019).

Genomic Prostate Score

This assay incorporates 12 cancer genes that represent four biological pathways of prostate cancer oncogenesis: the androgen receptor pathway, cellular organization, stromal response, and proliferation. A 20-point increase in the genomic prostate score (GPS) is associated with a statistically significant increased risk for high-grade and/or non–organ-confined disease (odds ratio

[OR] 1.9, 95% CI 1.3 to 2.9) (Brand et al., 2016; Cullen et al., 2015).

Cell Cycle Progression

This analyzes 31 cell-cycle–related genes and 15 housekeeping genes by quantitative reverse transcription polymerase chain reaction (RT-PCR). In one cohort of 349 men managed without primary treatment, the cumulative incidence of death was increased among those with cell cycle progression (CCP) scores greater than 2 (19% of the population) compared with those with lower CCP scores (Cuzick et al., 2012, 2015). Patient outcomes could not be differentiated in those with lower CCP scores. The HR of prostate cancer death was 1.7 per unit increase in CCP score to 10 or Cancer of the Prostate Risk Assessment (CAPRA) high-risk disease.

In patients with a strong family history of prostate, breast, and/or ovarian cancer, germ line testing for DNA repair defects (BRCA, ATM, etc.) is warranted. One study of men with DNA repair defects managed with active surveillance found that men with BRCA2 mutations had a 2.8 greater risk of progression to higher grade cancer. Since these mutations increase the rate of acquisition of a mutuational burden, the presence of a germ line DNA repair defect, particularly BRCA2, is a contraindication to surveillance (Carter et al., 2019).

Caveats of Tissue-Based Genomics

There are two major limitations of tissue-based genomic testing. The first is genetic heterogeneity. A recent study performed exomewide sequencing of individual prostate cancers microdissected from patients with multifocality. The genes utilized in the GC, GPS, and CCP assays described earlier were then compared (Wei et al., 2017). Marked heterogeneity of the scores of all three tests between cancers from the same prostate was observed. The confounding problem of genetic heterogeneity of individual cancers in the same gland is considerable.

A second important consideration in the Gleason 6 population is the "Bayesian" problem, related to the low *a priori* risk for metastasis. Thus if a patient with Gleason 6 cancer has a 3% chance of metastases at 15 years and a genetic biomarker has a specificity of 90% for significant cancer, the risk for overdiagnosis of significant cancer may be three times higher (10% vs. 3%) than the risk for metastases. Therefore genetic testing of the tissue should be restricted to higher-risk patients. This includes patients with high cancer volume on biopsy, those with high PSA density, or those with Gleason 7 who are surveillance candidates.

Key Points

- Misattribution of grade (25% to 30% of cases) is much more common than true biologic progression from Gleason 3 to 4 or 5 (1% to 2.3% per year).
- Factors that increase the risk for coexistent higher-grade cancer include PSA density (>0.15), race (African-American), and volume of cancer on biopsy (number of positive cores, extent of core involvement).
- Newly diagnosed men on active surveillance should have a confirmatory biopsy within 1 year, targeting the undersampled areas of the prostate.
- After this, they should have PSA every 6 months and periodic repeat biopsy (every 3 to 5 years).
- MRI and targeted biopsy may replace serial systematic biopsies in very-low-risk men. Because the NPV of MRI is a function of underlying risk, those at higher risk still warrant systematic biopsies.

Psychological Aspects

There is no evidence that adverse psychological effects are significant in men on active surveillance. Anxiety accompanies a diagnosis of prostate cancer, but seems to be influenced less by treatment. In the Scandinavian trial comparing radical prostatectomy to watchful waiting (without the option of definitive intervention), there was no difference in psychological functioning, anxiety, or depression between the two groups (Johansson et al., 2011).

However, the uncertainty of living with untreated cancer creates an undeniable psychological burden and may influence patient adherence to active surveillance. In the large cohorts of active surveillance, 10% to 15% of men elect to have treatment without a predefined indication (e.g., grade progression, rapid PSA increase). Men on surveillance have specific survivorship needs, related to reassurance and avoidance of psychological distress. Patient anxiety over time has been evaluated within the PRIAS study (van den Bergh et al., 2010). Somewhat counterintuitively, patient-reported anxiety and uncertainty about treatment decisions were lower in the surveillance group than in men who had definitive therapy. Anxiety did not increase over time. In fact, patients' confidence in their decision increases with time, as, with the passage of years, they experience no evidence of disease progression.

Several studies have identified those patients who do not fare well on surveillance. This includes those with chronic anxiety disorders and social isolation. Overall physical health correlates with reduced rates of anxiety and distress.

Lifestyle Management

For many men on active surveillance, their urologist is the only physician they see on a regular basis. This is therefore an opportunity to counsel patients regarding their overall health status and encourage them to adopt a healthy lifestyle. These lifestyle changes are discussed in the following sections.

Smoking Cessation

Advising men to quit smoking is the single most cost-effective health intervention in the entire edifice of medical practice. Although prostate cancer is not as closely linked to smoking as lung cancer or bladder cancer, the literature suggests that smoking may promote the development of more aggressive disease and increase disease-specific mortality (Kenfield et al., 2011a). Quitting seems to reduce this risk and also has other obvious health benefits. The patient with newly diagnosed cancer seeing a “specialist” is uniquely primed and receptive to this advice. Two minutes spent by the specialist in counseling smoking cessation may have an impact on a patient's smoking behavior. A patient who stops smoking because of this intervention will derive a great deal more benefit with respect to longevity and general health than any prostate cancer intervention is likely to provide!

Exercise

Regular exercise is a powerful health-promoting intervention. If it were a pill, everyone would take it! Regular exercise may inhibit the risk for prostate cancer prevention in many ways (Friedenreich et al., 2016; Galvão et al., 2016; Giovannucci et al., 2005; Kenfield et al., 2011b; Johnsen et al., 2009; Nilsen et al., 2006; Orsini et al., 2009). These include modulation of circulating growth factors and sex-steroid hormones; improved myokine and adipokine profiles; improved immune function; androgen receptor adaptation; reduction in systemic inflammation and oxidative stress; changes in tumor vascularization; modification of expression of a number of key regulatory genes; and alteration of telomeres (Nilsen et al., 2006). This is particularly true for strenuous exertion, that is, activity that requires an energy expenditure six or more times the resting metabolic rate. One group reported that more than 3 hours per week of vigorous activity in treated prostate cancer patients reduced the disease-specific mortality by 61% (Kenfield et al., 2011b). Brisk walking of 7 hours or more per week had a similar benefit. A Canadian long-term study with 17-year follow-up reported a 45% reduction in disease-specific mortality (Friedenreich et al., 2016). Given the many health benefits, counseling patients on surveillance regarding the importance of regular exercise is warranted.

Weight Control

Obesity contributes to prostate cancer progression in many ways, including alterations in leptin and adiponectin, which may play tumor-suppressor roles; increase in IGF-1 and decrease in IGF binding proteins 1 and 2, resulting in increased mitogenic signaling; lower sex hormone–binding protein and higher estrogen; increased systemic inflammation and oxidative stress; and increased insulin levels (Bandini et al., 2017). Many studies have reported an increase in high-grade cancer and prostate cancer mortality in obese men, independent of diet, physical activity, or clinical factors (Agalliu et al., 2015; Amling et al., 2004; Barrington et al., 2015; Bassett et al., 2005; Cao and Ma, 2011; Giovannucci et al., 2007; Haque et al., 2014; Kane et al., 2005; Ma et al., 2008; Moller et al., 2015; Pischon et al., 2008; Rodriguez et al., 2001; Strom et al., 2005; Yamoah et al., 2016). A recent meta-analysis estimated that a 5-kg/m^2 increase in body mass index (BMI) increased the risk for prostate cancer mortality by 20% (Barrington et al., 2015); a 0.1-unit increase in waist/hip ratio was associated with a similar increase (Cao and Ma, 2011). This relationship may be particularly strong in African-Americans (Pischon et al., 2008). Thus men should be counseled regarding the importance of maintaining a healthy weight.

Diet

Whether dramatic changes in diet and lifestyle will translate into a reduced risk for disease progression and mortality has not been proven. Most data come from epidemiologic studies or studies in treated patients, rather than specifically from studies of men on surveillance. However, a reasonable inference is that dietary modification can have a significant influence on the natural history of prostate cancer. To summarize a large body of diverse literature: men with prostate cancer on active surveillance should focus on consuming a varied diet rich in vegetables, especially cooked tomatoes and cruciferous vegetables, whole grains, skinless poultry, and fish, and limit meat consumption, especially processed meats (Peisch et al., 2017; Venkateswaran and Klotz, 2010). A prostate-healthy diet is essentially the same as a heart-healthy diet (Lin et al., 2019). One study examined comprehensive lifestyle modification including a vegan diet, exercise, and stress management. The study reported a decrease in PSA, improved treatment-free survival, and a favorable alteration in number of prostate cancer–related genes, and telomere length (Frattaroli et al., 2008; Ornish et al., 2008, 2013). This emphasized the positive effects of this approach in both the biologic and psychological spheres.

For patients or physicians who wish to be extremely proactive in this area, the approach of "holistic surveillance," utilizing a vegan diet and a wide range of micronutrients, has been described (Berg et al., 2016). This approach, although appealing to individuals committed to complementary medicine, is unproven. Further, high-dose micronutrients may be harmful and in the absence of evidence should be avoided (see next section).

Micronutrients

In general, there are no specific vitamins or supplements that have been demonstrated to be of value in men on active surveillance. Indeed, most large professional bodies do not recommend nutritional supplements for cancer prevention, either primary or secondary. The American Cancer Society 2012 summary on this topic states, "Evidence from both observational studies and clinical trials suggests that dietary supplements are unlikely to improve prognosis or overall survival after the diagnosis of cancer, and may actually increase mortality" (Rock et al., 2012).

An exception is vitamin D. Vitamin D deficiency is common in the elderly, particularly in Northern latitudes (Cashman et al., 2016; Chapuy et al., 1997). Low levels of vitamin D have been linked to prostate cancer. One study in a surveillance population reported a seasonal variation in PSA rise (slower in summer months), suggesting a beneficial role of higher levels of vitamin D (Vieth et al., 2006). Studies evaluating the role of vitamin D in overall cancer and cardiovascular disease prevention are ongoing.

Capsaicin, the active "hot" ingredient in red chili peppers, is a biologically active molecule that targets a number of prostate cancer–related pathways and may be useful in secondary prevention. In animal models, it significantly inhibits prostate cancer growth and induces apoptosis and cell cycle arrest (Venier et al., 2015). However, there is no evidence to date of its effectiveness in the active surveillance scenario.

Caution regarding the holus-bolus, enthusiastic adoption of unproven micronutrients is warranted. A recent selenium study of 4400 men with localized prostate cancer reported that those consuming greater than or equal to 140 µg/day of supplemental selenium after diagnosis had a 2.6 times greater disease-specific mortality (Kenfield et al., 2015). Patients taking vitamin E in the SELECT trial had an increased risk for prostate cancer compared with placebo (Klein et al., 2011). These micronutrients are generally contraindicated in men on active surveillance.

Pharmacologic Intervention

5α-reductase–specific antibodies (5ARIs) have a theoretical role in men on active surveillance by reducing the androgenic load. It is well known that men with 5α-reductase deficiency do not develop prostate cancer (Nelson et al., 2003). The Reduction by Dutasteride of Clinical Progression Events in Expectant Management of Prostate Cancer (REDEEM) study compared dutasteride to placebo in men on active surveillance (Fleshner et al., 2012). The primary end point was the rate of "progression," defined as volume progression of Gleason grade 1 beyond Epstein criteria, or grade progression. There was a 38% reduction in the rate of progression, but this was entirely a result of reduced numbers of patients with GG1 volume progression. This is not surprising, considering that the 5ARIs induce epithelial cytoreduction. There was no difference in upgrading between the two groups. Adverse effects on libido and erectile function were more common in the dutasteride group.

Given the effect of 5ARIs on libido, and lingering uncertainty about a slight increase in upgrading in the Reduction by Dutasteride of Prostate Cancer Events (REDUCE) trial and the Prostate Cancer Prevention Trial (PCPT), 5ARIs should not be used in men on active surveillance solely for prevention of "progression," or for PSA reduction. However, in men on active surveillance who have a benign prostatic hyperplasia/lower urinary tract symptom indication for a 5ARI, the prior diagnosis of low-grade prostate cancer should not influence the treatment decision.

Statins, which reduce cholesterol by inhibiting HMG-CoA (3-hydroxy-3-methyl-glutaryl-coenzyme A) reductase, may have a secondary chemoprevention role in men on active surveillance. Statins reduce lipid rafts, which may promote prostate cancer progression via the androgen receptor (AR), epidermal growth factor receptor (EGFR), and luteinizing hormone receptor (LHR) pathways, resulting in attenuated Akt signaling and apoptosis (Zhuang et al., 2005), as well as anti-inflammatory and anti-angiogenic effects (Demierre et al., 2005). Chronic inflammation is associated with an increased risk for prostate cancer, and the inhibitor effect on inflammation is a plausible mechanism for a statin prevention pathway (Allott et al., 2017). Statins may also inhibit androgen synthesis. They have been demonstrated to have a beneficial effect on prostate cancer progression in numerous, mostly epidemiologic, studies, and in men treated radically with surgery or radiation (Babcook et al., 2016). One study of

11,772 men with localized prostate cancer reported a postdiagnostic use of statins reduced disease-specific mortality by 24% (Yu et al., 2014), and another showed a 36% reduction in PSA recurrence (Allott et al., 2014). However, some studies failed to show a benefit (Chao et al., 2013; Ishak et al., 2014; Mondul et al., 2011). Given the benefits of lower cholesterol on cardiovascular health, particularly in men with underlying risk factors, the use of statins in many men with active surveillance seems reasonable.

Metformin reduces hepatic glucose production, increases insulin sensitivity, and increases glucose utilization. It has potential antineoplastic properties through multiple pathways including AMP-activated protein kinase–dependent and kinase-independent pathways, alteration of insulin and IGF signaling, and suppression of androgen signaling by reducing cyclin D1 activity (Hankinson et al., 2017; Miller et al., 2013; Zhang and Guo 2016).

A number of studies have demonstrated that diabetics on metformin have a decrease in prostate cancer–specific mortality (Margel et al., 2013; Spratt et al., 2013). However, several studies have not shown such a relationship (Allott et al., 2013; Mayer et al., 2017; Patel et al., 2010). Several studies are currently evaluating the role of metformin, specifically in men on active surveillance. Until further evidence is forthcoming, metformin is not indicated for secondary prevention in men on active surveillance.

Summary

Clinicians managing patients on active surveillance should use the opportunity of regular follow-up visits to counsel patients about the benefits of dietary and lifestyle modifications. These simple recommendations, which also benefit general and cardiovascular health, should include the following:

1. Exercise regularly, and include vigorous activity if possible.
2. Maintain a healthy weight.
3. Stop smoking.
4. Eat a vegetable- and grain-based diet; moderate red meat consumption, especially processed meats; if eating meat, rely on fish and skinless poultry.
5. Limit saturated fat intake.
6. Take vitamin D, 1000 to 2000 IU/day, especially during periods of reduced sunlight.
7. Consider a low-dose statin.

GAP 3

A major undertaking in this field has been the development of a global database of men on active surveillance. This extraordinary initiative, known as Global Action Plan Prostate Cancer Active Surveillance (GAP3), was funded by the Movember Foundation as part of their Global Action Plan initiative. The GAP3 initiative connected more than 250 researchers with an interest in active surveillance from virtually every region in the world. The initiative will address a number of key questions, including how to define low-risk prostate cancer; how best to establish a diagnosis; the role of comorbidity and life expectancy; the best monitoring tools and how to use them; how to define optimal triggers for active treatment and switch to watchful waiting; and criteria to evaluate the efficacy of active surveillance. The goal is to create an international consensus on these questions. This has been achieved to some degree (Bruinsma et al., 2017). With longer follow-up and increased incorporation of imaging and biomarkers, the data from this initiative will likely set an international standard for active surveillance.

Barriers to Active Surveillance

Important barriers can hinder a patient's decision to choose active surveillance. The evidence for this is the relatively low rate of uptake of active surveillance in many constituencies (Aizer et al., 2012; Cooperberg, 2015; Harlan et al., 2003). These include patient preconceptions about the meaning of “cancer”; misinformation provided to the patient by friends, family, or practitioners; provider preference/bias against active surveillance; and psychological factors. These can lead to difficulties in making the correct decision and poor health outcomes. How can these barriers to active surveillance be overcome? Patients need to be equipped with the correct information, and shared decision making must be supported by health care professionals. The key steps are to (1) inform patients about the multiple reasonable available options, and (2) thoroughly discuss these while balancing them with the patient's own preferences and values. Better-informed patients tend to prefer conservative management (Volk et al., 2014). A good decision aid can be invaluable in this process; a number of these specifically geared to the low-risk patient have been developed and are available online (Adsul et al., 2015; Ilic et al., 2015; Lin et al., 2009; Volk et al., 2007).

Shared decision making is the cornerstone of this approach. This implies four requisites (Charles et al., 2003). Each of these has communication skills as a central component:

1. Both physician and patient are involved in the decision-making process.
2. Both share information with each other.
3. Both take steps to participate in the decision-making process by expressing treatment preferences.
4. A decision is made, and both the physician and patient agree on this.

Physicians, in other words, should serve as the navigator, not the driver, of this process. Active surveillance is a journey, not just a destination. It has complexity influenced by many individual and contextual factors. Clinicians should be aware of these. Internal factors (i.e., patient values) and external factors (pressure brought to bear on the patient) both exert an influence leading to a final decision, and a shared decision-making approach led by a physician skilled in this technique is critical.

Active surveillance may have an impact on QoL in several respects:

1. Prostate biopsy: Of studies addressing the association between biopsies and erectile dysfunction and incontinence, three of four show none exists (Hilton et al., 2012; Parker et al., 2016; Pearce et al., 2015), and one showed an association (Fujita et al., 2009). This question warrants further evaluation.
2. Anxiety: Studies that address this generally report that men on active surveillance have a low rate of anxiety. Anxiety occurs with the diagnosis of prostate cancer, but is not increased by the selection of conservative management. A limitation of these studies is that they have been derived from men self-selecting for active surveillance.
3. GU QoL: Several long-term studies have reported good or better prostate-specific function and QoL than those who received active treatment (de Cerqueira et al., 2015; Jeldres et al., 2015; Pham et al., 2016; van den Bergh et al., 2012, 2014; Venderbos et al., 2017; Watson et al., 2016). Improved QoL was consistently seen using validated questionnaires covering voiding and sexual function (e.g., EORTC QLQ PR25, IIEF-15 score, FACT-P, EPIC). The QoL is comparable to that of men without prostate cancer. A limitation is a paucity of long-term data, and disentangling late treatment effects from aging effects on physical function is challenging.

Every active surveillance cohort reports a subset of men who discontinue active surveillance on their own, without meeting the criteria for intervention. This ranges from 7% to 15% in the quoted studies. In one systematic review of 17 studies, 20% discontinued active surveillance because of patient choice or anxiety (Simpkin et al., 2015). The proportion differs substantially among cohorts. QoL assessment on these patients is often discontinued, making assessment about the impact of treatment in the active surveillance cohort on QoL difficult.

Nomenclature

A continual challenge in the management of men on active surveillance is the impact of the word *cancer* on a patient's emotional response to his diagnosis, and his decisions regarding treatment. Patients understandably fear that they have an aggressive, lethal disease. In the context of the indolent, nonmetastatic characteristics of low-grade prostate cancer, it has been proposed that Gleason 6 be renamed. Two suggestions include indolent lesion of epithelial origin (IDLE) (Esserman et al., 2014) and prostatic neoplasm of low malignant potential (PNLMP). This change in nomenclature would have the benefit of reducing patient anxiety, facilitating conservative management, and enhancing retention of men on surveillance.

The problem with dropping the word *cancer* is that Gleason 6 cancer does fulfill the traditional pathological criteria for cancer. It can invade locally. The mutational landscape between Gleason 6 and higher-grade cancer is a continuous one; some Gleason 6 cancers harbor potentially significant mutations. Finally, metastatic phenotype is not a requirement for designating a lesion cancerous. Basal cell cancers of the skin and gliomas are two examples of nonmetastasizing cancers. Therefore it is unlikely that the term *cancer* will be discontinued.

Finally, the shift to the Gleason grade group system, whereby low-grade cancer has a score of 1 (rather than 6) has achieved many of the benefits discussed earlier.

Economics

The cost of prostate cancer management is high. This is a function of both the high prevalence and the cost of therapy. Active surveillance requires long-term follow-up, and this engenders costs. In general, however, these costs are less than those of active treatment. Clearly, overtreatment is costly, both in terms of the financial impact of unnecessary treatment and the personal cost to the individual's QoL.

One study calculated that for low-risk prostate cancer patients, the cost of definitive therapy compared with no active treatment within 1 year was over $18,000 per patient (Keegan et al., 2012). The costs of surveillance are a function of the frequency and type of diagnostic tests, and the rate of radical intervention. One Canadian study, which included the effects of other-cause mortality and cancer recurrence, calculated a cost savings of $100 million at 10 years compared with immediate treatment of all men (Dragomir et al., 2014).

Reducing the rate of biopsy significantly reduces cost. Biannual biopsies result in comparable costs to surgery by 10 years (Keegan et al., 2012). Cost savings are also dependent on a significant proportion of patients remaining on active surveillance long-term. In the two longest-term studies to date, the retention on surveillance at 15 years was 43% and 55% (Klotz et al., 2015; Tosoian et al., 2015). The increased utilization of MRI and biomarkers has the potential to add considerable expense. However, these technologies may prove to be cost-effective by improving patient selection, reducing the need for treatment, and reducing the need for repeat biopsies. For MRI in particular, there is a very wide range in cost, from less than $500 (UK National Health Service) to ten times that amount (some US private practices). Improvements in MRI efficiency and competition may bring these higher prices down over time. A scenario whereby MRI is performed every 3 to 5 years on surveillance patients, at a cost of under $1000, with an accuracy that allows biopsy to be avoided in most patients with a negative or stable MRI, is likely to be quite cost-effective compared with definitive therapy.

Research Questions

The controversies and unanswered questions in this field have moved from concept to application. Initial conservative management for low-risk disease is supported by preclinical genetic analysis, randomized trials (PIVOT, ProtecT), and prospective series of conservative management reviewed in this chapter. The major focus during the past decade was to reduce overtreatment. Now, the major concern is avoiding undertreatment in those whose risk is higher than anticipated. The questions are now related to who is a candidate for active surveillance, how they should be followed, when and at what interval diagnostic tests should be undertaken, and which tests are optimal. The areas of uncertainty cover a broad swath of current research in prostate cancer. Research is warranted at the molecular (genomic, proteomic, transcriptomic), epigenetic, epidemiologic, radiologic, and clinical trial levels.

The key questions are as follows: What are the molecular events that signal progression of low-grade disease? We are just at the beginning of learning which genetic and epigenetic aberrations alter the behavior of prostate cancer cells. Many tantalizing mechanisms have recently been identified; for example, the effect of circulating exosomes containing biologically active molecules, that is, mRNA, shed by more aggressive cancer cells and incorporated into low-grade cells resulting in more aggressive behavior. Another priority is determining whether patients with certain known germline mutations, for example, *BRCA1* or *BRCA2*, are candidates for surveillance. *BRCA* mutations confer marked genetic instability, and recent studies indicate that the mutational load of localized prostate cancer resembles that of castration-resistant prostate cancer, making these patients unreliable candidates for conservative management. We will learn much more about how these aberrant genetic pathways interact over the next decade. The behavior of prostate cancer in men with DNA repair germline defects and the role of screening for these defects and mutations is currently the subject of intense interest. Given what is known about the rapid accumulation of a large mutational burden in men with these germline abnormalities, active surveillance should be offered with caution to men with a known germline mutation of the DNA repair pathway (*BRCA1* and *BRCA2*, *ATM*).

How do we best identify the “wolf in sheep's clothing” (Schoots et al., 2017)? The limitation of active surveillance based on systematic biopsy is the misattribution of low-grade cancer in the 25% to 30% of patients who harbor a higher-grade cancer that was missed because of sampling. The increased use of MRI will address this substantially but not completely. We know much better today how to use baseline parameters to identify patients at risk (e.g., PSA density, extent of core involvement, race). The use of MRI and molecular biomarkers is further refining this, but uncertainty remains as to the reliability of mpMRI, the relationship between underlying risk and the need for systematic biopsies if the MRI is normal, and the role of molecular biomarkers. Other accurate imaging methods are emerging to identify significant cancer, including PSMA-PET, and high-resolution microultrasound.

Nomograms incorporating MRI and/or biomarker findings to predict the risk for coexistent higher-grade cancer are needed urgently. Sorting out how to use these tests optimally will require further research. For example, does the presence of restricted diffusion whose targeted biopsy shows Gleason grade 1 mean the patient has a biologically more aggressive cancer? Was a higher-grade cancer missed, or is it a false-positive MRI? The role of a genetic biomarker in this setting seems obvious, but there are little data on this situation. The field of radiomics, that is, the molecular events associated with restricted diffusion and other MRI abnormalities associated with cancer, is in its infancy. Similarly, the best strategy for a patient with microfocal Gleason 6 cancer whose Prolaris or Oncotype DX assay reveals a mildly elevated risk score is unclear. MRI with targeted biopsy also likely plays a role in this setting, but there are few data.

Which intermediate-risk patients are candidates for surveillance? Recent data, described in this chapter, indicate that the approach to surveillance, based on PSA and serial biopsy, is imperfect for Gleason 7 patients. Despite close monitoring and selective delayed intervention, 20% or more of these patients progress to metastasis by 15 years. Yet the glass is also more than half full; 80% remained free of metastases. Obviously, therefore, many intermediate-risk patients are candidates for surveillance. The key is to identify those with indolent disease accurately. Further studies using molecular biomarkers and MRI to select these patients are warranted.

The field of liquid biopsy, enabling a “global” assessment of the patient's mutational load, offers a lot of promise in this area.

Once patients have been selected for surveillance, a host of research questions present themselves. Which interventions (diet, exercise, micronutrients, and pharmacologic agents) are warranted to reduce the risk for biologic progression? This is a fruitful area for research. Many ongoing studies are evaluating the role of exercise, dietary modification, and naturally occurring micronutrients in men on surveillance. These patients are followed for many years; they are motivated, and a great deal of evidence suggests that prostate cancer progression is amenable to modification by dietary or other influences. Specific questions include the role of exercise, weight loss, reduction of animal protein or carbohydrate in the diet, and the use of natural dietary micronutrients, including pomegranate, capsaicin, and lycopene. A host of other compounds have been suggested as being useful in the surveillance setting, but are unproven. Often, micronutrients that look promising turn out to be harmful when studied in rigorous clinical trials. Common drugs with metabolic or cardiovascular benefits look promising, particularly statins and diabetic medications (i.e., metformin). Clinical intervention trials testing these agents are warranted.

What is the most efficient and cost-effective way to follow patients longitudinally? Is serial biopsy still required, and in whom? Can risk stratification allow patients to minimize the burden of follow-up? These questions have both QoL and economic ramifications. An unmet need in the field is to reduce excessive reliance on serial biopsy. Can MRI, if negative, replace systematic biopsy, and can targeted biopsy alone (i.e., 2 to 4 cores) replace the 12- to 14-core systematic approach? Can patients with a negative molecular biomarker avoid or reduce the frequency of biopsies? Is the negative predictive value of a negative MRI sufficiently high that a biopsy can be safely avoided, and how does the NPV vary according to patient risk? Aside from discontinuing surveillance because of short life expectancy, are there patients whose disease is so predictably indolent that no further follow-up is required despite a 15- to 20-year life expectancy? How do we identify these?

Several national health policy groups have recommended against PSA screening, largely because of the risk for overdetection and overtreatment. Can the widespread adoption of surveillance for low-risk disease rehabilitate prostate cancer screening and satisfy policy makers and methodologists that the benefits outweigh the risks at an acceptable cost? This will require modeling studies based on recent data.

Conclusion

Active surveillance has been widely adopted as a safe and effective strategy for men with low-risk prostate cancer. It is considered the primary treatment for most of these men by numerous national organizations, including the AUA and ASCO. It is an important antidote to the dilemma of overtreatment that accompanies screening and early detection. Although the concept is robust, many aspects of surveillance are still in the process of being defined, particularly the role of serial imaging and molecular biomarkers.

Open Radical Prostatectomy

Edward M. Schaeffer MD, PhD, Alan W. Partin MD, PhD, Herbert Lepor MD

There is no better way to cure cancer that is confined to the prostate than total surgical removal. Radical prostatectomy is the only form of treatment for localized prostate cancer that has been shown in a randomized controlled trial to reduce progression to metastases and death from the disease (Bill-Axelson et al., 2008; Holmberg et al., 2002). Furthermore, on the basis of improved understanding of the periprostatic anatomy, today less bleeding and improved rates of postoperative continence and potency are seen (Nielsen et al., 2008; Walsh, 1998, 2000).

Technically, radical retropubic prostatectomy (RRP) is one of the most difficult operations in the field of urology. The three goals of surgery, in order of importance, are cancer control, preservation of urinary control, and preservation of sexual function. Great skill and experience in the selection of surgical candidates and operative technique are necessary to achieve all three. This chapter summarizes our experience, with the hope that it will shorten the reader's learning curve. Video 155.1▶ demonstrates a detailed description of the surgical technique (Walsh and Garcia, 2004).

Radical Retropubic Prostatectomy: Surgical Anatomy

Venous and Arterial Anatomy

The veins of the prostate drain into the Santorini plexus. It is necessary to have a complete understanding of these veins to avoid excessive bleeding and to ensure a bloodless field in exposing the membranous urethra and the apex of the prostate. **The deep dorsal vein leaves the penis under the Buck fascia between the corpora cavernosa and penetrates the urogenital diaphragm, dividing into three major branches: the superficial branch and the right and left lateral venous plexuses** (Reiner and Walsh, 1979) (Fig. 155.1). The superficial branch, which travels between the puboprostatic ligaments, is the centrally located vein overlying the bladder neck and prostate. This vein is easily visualized early in retropubic operations and has communicating branches over the bladder itself and into the endopelvic fascia. The superficial branch lies outside the anterior prostatic fascia.

FIG. 155.1 Location of the superficial and deep branches of the dorsal vein as they travel over the anterior and anterolateral surfaces of the prostate. Note the common trunk located immediately over the urethra. This is the site where the dorsal vein is transected. The pelvic plexus: The autonomic innervation of the pelvic organs arises from the pelvic plexus, which is formed by parasympathetic fibers that arise from the sacral center

(S2–S4) and sympathetic fibers via the hypogastric nerve from the thoracolumbar center. The pelvic plexus provides visceral branches that innervate the bladder, ureter, seminal vesicles, prostate, rectum, membranous urethra, and corpora cavernosa. The branches that innervate the corpora cavernosa enter in a spraylike distribution 20 to 30 mm distal to the junction of the prostate and bladder, where they continue distally posterolateral to the prostate. *n.,* nerve. (© Brady Urological Institute.)

The common trunk and lateral venous plexuses are covered and concealed by the prostatic and endopelvic fascia. The lateral venous plexuses traverse posterolaterally and communicate freely with the pudendal, obturator, and vesical plexuses. Near the puboprostatic ligaments, small branches from the lateral plexus often penetrate the pelvic sidewall musculature and communicate with the internal pudendal vein. The lateral plexus interconnects with other venous systems to form the inferior vesical vein, which empties into the internal iliac vein. With the complex of veins and plexuses anastomosing freely, any laceration of these friable structures can lead to considerable blood loss.

The prostate receives arterial blood supply from the inferior vesical artery. According to Flocks (1937)**, after the inferior vesical artery provides small branches to the seminal vesicle and the base of the bladder and prostate, the artery terminates in two large groups of prostatic vessels: the urethral and capsular groups** (Fig. 155.2). The urethral vessels enter the prostate at the posterolateral vesicoprostatic junction and supply the vesical neck and periurethral portion of the gland. The capsular branches run along the pelvic sidewall in the lateral pelvic fascia posterolateral to the prostate, providing branches that course ventrally and dorsally to supply the outer portion of the prostate. The capsular vessels terminate as a small cluster of vessels that supply the pelvic floor. On histologic examination, the capsular arteries and veins are surrounded by an extensive network of nerves (Lepor et al., 1985; Lue et al., 1984; Walsh and Donker, 1982; Walsh et al., 1983). **These capsular vessels provide the macroscopic landmark to aid in the identification of the microscopic branches of the pelvic plexus that innervate the corpora cavernosa.**

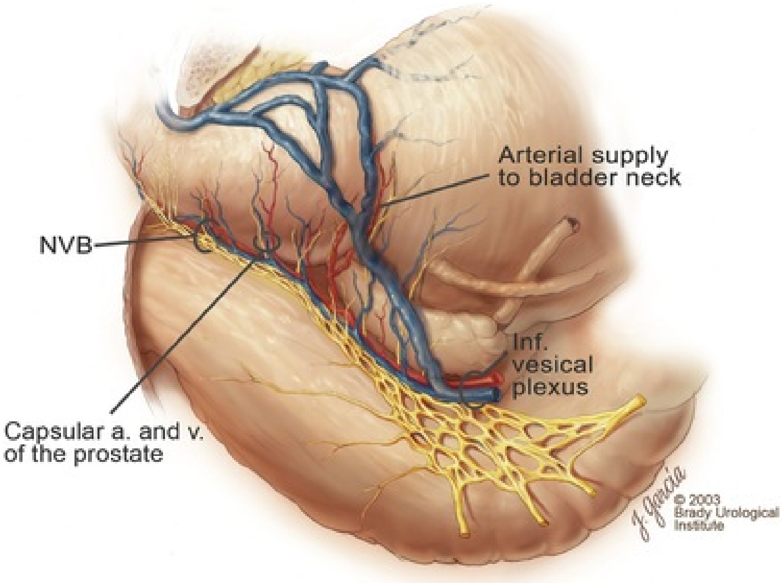

FIG. 155.2 Arterial supply to the prostate. The inferior vesical artery terminates in two large groups of vessels. One group, the urethral vessels, enters the prostate at the posterolateral vesicoprostatic junction to supply the bladder neck and periurethral portions of the gland. The second group, the capsular branches, runs along the pelvic sidewall in the lateral pelvic fascia posterolateral to the prostate, providing branches that course ventrally and dorsally to supply the outer portion of the prostate. These capsular arteries and veins are intimately associated with the branches of the pelvic plexus forming the neurovascular bundle (NVB), which is used as the macroscopic landmark to aid in the identification of the microscopic branches of these nerves. Note at the apex that small branches of the nerves travel anteriorly away from the vessels. *a.,* artery; *inf.,* inferior; *v.,* vein. (© Brady Urological Institute.)

The major arterial supply to the corpora cavernosa is derived from the internal pudendal artery. However, **pudendal arteries can arise from the obturator, inferior vesical, and superior vesical arteries. Because these aberrant branches travel along the lower part of the bladder and anterolateral surface of the prostate, they are divided during radical prostatectomy.** This may compromise arterial supply to the penis, especially in older patients with borderline penile blood flow (Breza et al., 1989; Polascik and Walsh, 1995; Rogers et al., 2004).

Pelvic Plexus

The autonomic innervation of the pelvic organs and external genitalia arises from the pelvic plexus, which is formed by parasympathetic, visceral,

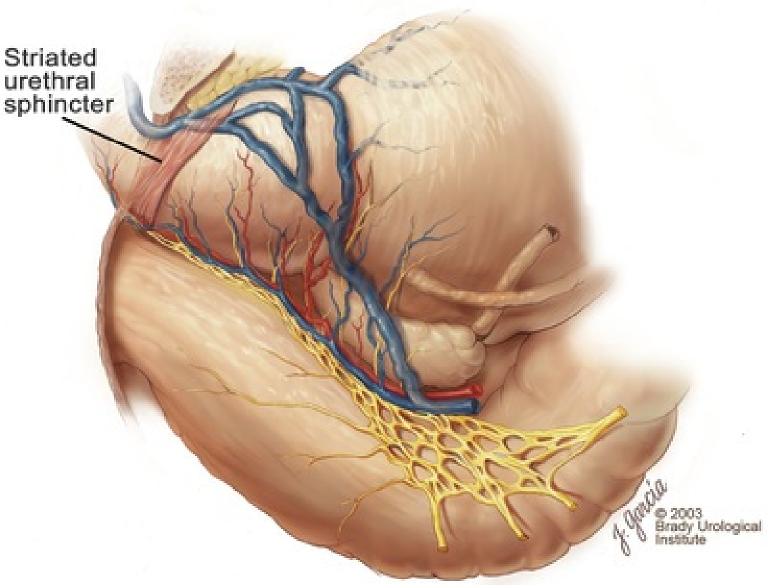
efferent, preganglionic fibers that arise from the sacral center (S2 to S4), and sympathetic fibers via the hypogastric nerve from the thoracolumbar center (Lepor et al., 1985; Lue et al., 1984; Schlegel and Walsh, 1987; Walsh and Donker, 1982; Walsh, 2007) (see Fig. 155.1). The pelvic plexus in men is located retroperitoneally beside the rectum 5 to 11 cm from the anal verge and forms a fenestrated rectangular plate that is in the sagittal plane with its midpoint at the level of the tip of the seminal vesicle.

The branches of the inferior vesical artery and vein that supply the bladder and prostate perforate the pelvic plexus. For this reason, ligation of the so-called *lateral pedicle* in its midportion not only interrupts the vessels but also transects the nerve supply to the prostate, urethra, and corpora cavernosa. The pelvic plexus provides visceral branches that innervate the bladder, ureter, seminal vesicles, prostate, rectum, membranous urethra, and corpora cavernosa. In addition, branches that contain somatic motor axons travel through the pelvic plexus to supply the levator ani, coccygeus, and striated urethral musculature. **The nerves innervating the prostate travel outside the capsule of the prostate and Denonvilliers fascia until they perforate the capsule where they enter the prostate.**

The branches to the membranous urethra and corpora cavernosa also travel outside the prostatic capsule in the lateral pelvic fascia dorsolaterally between the prostate and rectum (see Fig. 155.1). Although these nerves are microscopic, their anatomic location can be estimated intraoperatively by use of the capsular vessels as a landmark. This structure, which is referred to here as the neurovascular bundle (NVB), has been termed the *NVB of Walsh* (*Stedman's Medical Dictionary,* 2000) (see Fig. 155.2). As emphasized by Takenaka et al. (2004) and Costello et al. (2004), the cavernous branches join the capsular arteries and veins in a spraylike distribution to form the NVB 20 to 30 mm distal to the junction of the bladder and prostate (see Fig. 155.2). The NVBs are located in the lateral pelvic fascia *between* the prostatic fascia and the levator fascia. At the apex of the prostate, the branches of the nerves to the cavernous bodies and striated sphincter also have a spraylike distribution both anteriorly and posteriorly with wide variation (Costello et al., 2004; Takenaka et al., 2005). After piercing the urogenital diaphragm, the nerve branches pass behind the dorsal penile artery and dorsal penile nerve before entering the corpora cavernosa (Walsh and Donker, 1982).

Striated Urethral Sphincter

The external sphincter, at the level of the membranous urethra, is often depicted as a “sandwich” of muscles in the horizontal plane. However, Oelrich (1980) demonstrated clearly that the striated urethral sphincter with its surrounding fascia is a vertically oriented tubular sheath that surrounds the membranous urethra. In utero, this sphincter extends without interruption from the bladder to the perineal membrane. As the prostate develops from the urethra, it invades and thins the sphincter muscle, causing a reduction or atrophy of some of the muscle (Fig. 155.3).



Striated urethral sphincter
© 2003 Brady Urological Institute

FIG. 155.3 The striated urethral sphincter with its surrounding fascia is a vertically oriented tubular sheath that surrounds the membranous urethra. The dorsal vein complex travels through the sphincteric complex. (© Brady Urological Institute.)

In the adult, the fibers at the apex of the prostate are horseshoe shaped and form a tubular, striated sphincter surrounding the membranous urethra. Near the apex of the prostate, the edges fuse in the midline posteriorly (Fig. 155.4A). Thus, as Myers et al. (1987) have shown, the prostate does not rest on a flat, transverse urogenital diaphragm like an apple on a shelf, with no striated muscle proximal to the apex. Rather, the external striated sphincter is more tubular and has broad attachments over the fascia of the prostate near the apex. This has important implications in the apical dissection and reconstruction of the urethra for preservation of urinary control postoperatively (Walsh et al., 1990).

FIG. 155.4 (A) A cross section through the apex of the prostate demonstrating the relationship among the fascia surrounding the striated sphincter and smooth muscle of the urethra. Note that at this level, the striated sphincter circumferentially surrounds the urethra. Note that the neurovascular bundles *(NVBs)* are posterolateral to the circumferential striated sphincter. (B) A cross-section through the midportion of the prostate demonstrating the relationship among the levator fascia, Denonvilliers fascia, and prostatic fascia. Note that the NVBs are located between the layers of the levator fascia and prostatic fascia. In performing a proper nerve-sparing operation, the prostatic fascia must remain on the prostate. (© Brady Urological Institute.)

The striated sphincter contains fatigue-resistant, slow-twitch fibers that are responsible for passive urinary control. Active continence is achieved by voluntary contraction of the levator ani musculature, which surrounds the apex of the prostate and membranous urethra. Some fibers of the levator ani (levator urethrae, pubourethralis) surround the proximal urethra and the apex of the prostate and insert into the perineal body in the midline posteriorly (Myers, 1991, 1994). **The pudendal nerve provides the major nerve supply to the striated sphincter and levator ani.** When patients are instructed to perform sphincter exercises postoperatively, they are actually contracting the levator ani musculature. However, because the striated urethral sphincter has similar innervation, patients are exercising this important muscle as well. Somatic motor nerves traveling through the pelvic plexus provide additional innervation to the pelvic floor musculature (Costello et al., 2004, Takenaka et al., 2005; Zvara et al., 1994).

Pelvic Fascia

The prostate is covered with three distinct and separate fascial layers: Denonvilliers fascia, the prostatic fascia (also called the *capsule of the prostate*), and the levator fascia. Denonvilliers fascia is a filmy, delicate layer of connective tissue located between the anterior walls of the rectum and prostate (see Fig. 155.4B). This fascial layer extends cranially to cover the posterior surface of the seminal vesicles and lies snugly against the posterior prostatic capsule. This fascia is most prominent and dense near the base of the prostate and the seminal vesicles and thins dramatically as it extends caudally to its termination at the striated urethral sphincter. On microscopic examination, it is impossible to discern posterior and anterior layers of this fascia (Jewett et al., 1972). For this reason, one must excise this fascia completely to obtain an adequate surgical margin.

In addition to Denonvilliers fascia, the prostate is also invested with the prostatic fascia and levator fascia. Anteriorly and anterolaterally, the prostatic fascia is in direct continuity with the parenchyma of the prostate. The major tributaries of the dorsal vein of the penis and Santorini plexus travel within the anterior prostatic fascia. Laterally, the prostatic fascia fuses with the levator fascia, which covers the pelvic musculature, to form the lateral pelvic fascia (Fig. 155.5) (Myers, 1991, 1994). Posterolaterally, the levator fascia separates from the prostate to travel immediately adjacent to the pelvic musculature surrounding the rectum. **The prostate receives its blood supply and autonomic innervation between the layers of the levator fascia and prostatic fascia** (see Figs. 155.4B and 155.5).

In an effort to avoid injury to the dorsal vein of the penis and Santorini plexus during radical perineal prostatectomy, the lateral and anterior pelvic fasciae are reflected off the prostate. This accounts for the reduced blood loss associated with radical perineal prostatectomy. In performing RRP, the prostate is approached from outside these fascial investments. For this reason, the dorsal vein complex must be ligated and the lateral pelvic fascia must be divided (Walsh et al., 1983).

Surgical Technique

Preoperative Preparation

The preoperative assessment must include a focused review of systems; a complete medical, surgical, and anesthesia history; an inquiry of all prescription and nonprescription medications; a physical examination; and routine preoperative laboratory testing. Life-threatening complications associated with RRP are rare and include myocardial infarction, cerebrovascular accident (stroke), cardiac arrhythmias, pulmonary embolus, hemorrhage, and anesthesia reactions. The preoperative assessment must identify candidates who are at increased risk for these mortality events to intervene to attenuate these risks. The preoperative assessment should also identify factors that may add to the technical challenge of the surgical procedure, including prior abdominal or pelvic surgery and irradiation, prior transurethral surgery, extensive prostate biopsies, history of significant inflammatory bowel disease, prior use of mesh during inguinal or incisional hernia repair, and the size of the prostate. Although none of these factors are contraindications for RRP, a greater level of skill and experience may be required to minimize complications.

The observation that up to 15% to 20% of men develop an inguinal hernia after RRP implied that this surgical procedure directly predisposes to the development of hernia (Lodding et al., 2001; Nielsen and Walsh, 2005; Regan et al., 1996). Approximately 15% of men undergoing radical prostatectomy will have a coexisting inguinal hernia detected if an appropriate inguinal examination is performed (Lepor and Robbins, 2007). In most of these cases, the inguinal hernia is asymptomatic. These observations suggest that an RRP may transform an asymptomatic inguinal hernia into a symptomatic hernia. Therefore examination of the inguinal canal with the Valsalva maneuver should be performed, enabling pre-peritoneal hernia repairs at the time of the radical prostatectomy.

Surgery is deferred for 6 to 8 weeks after needle biopsy of the prostate and 12 weeks after transurethral resection of the prostate. This delay enables inflammatory adhesions or hematomas to resolve so that the anatomic relationships between the prostate and the surrounding structures return to a nearly normal state before surgery. This is especially important if one hopes to preserve the NVBs intraoperatively and avoid rectal injury.

Donation of autologous blood is not performed at our institutions because transfusion rates are less than 1%. Erythrocyte-stimulating proteins, which are not approved by the U.S. Food and Drug Administration (FDA), have been shown to raise the hematocrit on average 2.8 percentage points, diminishing postprostatectomy anemia (Rosenblum et al., 2000). High hematocrit at hospital discharge can improve the pace of recovery (Sultan et al., 2006).

The recommended prophylactic regimens for open or laparoscopic surgery involving entry into the urinary tract are a first- or second-generation cephalosporin or an aminoglycoside in combination with metronidazole or clindamycin (Wolf et al., 2008).

The preoperative management of anticoagulants and antiplatelet agents used for the treatment of specific medical conditions, such as prosthetic valves, atrial fibrillation, and coronary artery stent implants, should be performed in conjunction with the internist or cardiologist. With nearly 1 million coronary interventions occurring every year and the majority including an implant of a drug-eluting stent, managing prescribed antiplatelet therapy can create a dilemma in balancing the risks for stent stenosis and perioperative bleeding. In the majority of cases, stent thrombosis is a catastrophic event resulting in life-threatening complications (Cutlip et al., 2001). The optimal preoperative regimen is often best developed through communication between the surgical/anesthesia team and treating physician (Grines et al., 2007).

Patients are prescribed a clear liquid diet on the day before surgery, are requested to drink one-half bottle of magnesium citrate in the evening, and have an enema on the morning of surgery. Patients are admitted to the hospital on that day.

Special Instruments

RRP requires few special instruments. A fiberoptic headlight is essential because much of the procedure is performed beneath the pubis in an area where visualization can be difficult. A standard Balfour retractor with both narrow and wide malleable blades is useful during lymph node dissection and is necessary during radical prostatectomy to provide cranial and posterior retraction on the peritoneum and bladder. Coagulating forceps; small, fine, and regular right-angled clamps; Metzenbaum and Jamison scissors; and 2.5- to 4.5-power loupes are the only other specialized instruments that should be available.

Anesthesia, Incision, and Lymphadenectomy

General endotracheal anesthesia is the preferred anesthesia. The anesthesiologist is encouraged to maintain relative hypotension with systolic blood pressure of no more than 100 mm Hg and to limit the replacement of crystalloid to 1500 mL until the prostate is removed (Davies et al., 2004). The patient is placed in the supine position. The table can be flexed in obese men to increase the distance between the umbilicus and pubis.

The skin is prepared and draped in the usual way. A No. 16 Silastic Foley catheter is passed into the bladder, inflated with 20 mL of saline, and connected to sterile, closed, continuous drainage. The use of a 16-Fr catheter facilitates placement of sutures in the mucosa of the urethra. A right-handed surgeon always stands on the left side of the patient.

An extraperitoneal, lower abdominal incision is made extending from the pubis toward the umbilicus. The anterior fascia is incised down to the pubis, the rectus muscles are separated in the midline, and the transversalis fascia is opened sharply to expose the space of Retzius. Laterally, the peritoneum is mobilized off the external iliac vessels to the bifurcation of the common iliac artery. **Care is taken to preserve the soft tissue covering the external iliac artery that contains the lymphatics draining the lower extremity. Interruption of these lymphatics may lead to lower extremity edema and lymphocele formation.** This maneuver is accomplished without dividing the vas deferens. Next, a self-retaining Balfour retractor is placed. Exposure for the lymph node dissection is facilitated by placement of a narrow, malleable blade attached to the Balfour retractor beneath the mobilized vas deferens to displace the peritoneum superiorly and a deep Deaver retractor to retract the bladder medially.

Pelvic lymph node dissection is performed before the radical prostatectomy. The dissection begins on the ipsilateral side of the major tumor in the prostate by dividing the adventitia over the external iliac vein (Fig. 155.6). The lymphatics overlying the external iliac artery are preserved. The dissection proceeds beneath the external iliac vein out to the pelvic sidewall and then inferiorly to the femoral canal, where the lymphatic channels are ligated at a convenient point. There is no need to remove the Cloquet node. The dissection then proceeds cranially along the pelvic sidewall to the bifurcation of the common iliac artery, where the lymph nodes in the angle between the external iliac and hypogastric arteries are removed. Next, the obturator lymph nodes are removed with care to avoid injury to the obturator nerve. The obturator artery and vein are skeletonized but usually are left undisturbed and not ligated unless excessive bleeding occurs. The dissection then continues down to the pelvic floor, exposing the hypogastric veins. This is an extended dissection and removes more lymph nodes than a limited one, improving staging and providing potential therapeutic benefit in some patients (Allaf et al., 2004; Palapattu et al., 2004). A similar procedure is performed on the opposite side (Cadeddu et al., 1997; Sgrignoli et al., 1994).

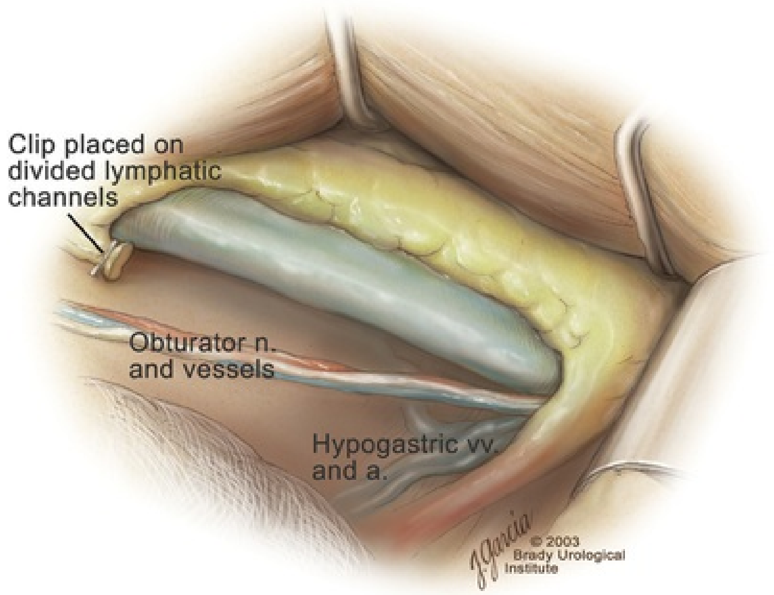

FIG. 155.6 View of the right pelvis after completion of the staging pelvic lymph node dissection. Note that the fibroadipose tissue overlying the external iliac artery has not been disturbed and that the obturator nerve, obturator vessels, and hypogastric veins *(vv.)* over the pelvic floor have been skeletonized. *a.,* artery; *n.,* nerve. (© Brady Urological Institute.)

Exposure

To expose the anterior surface of the prostate, it is necessary to displace the peritoneum superiorly. A malleable blade is used to retract the peritoneum superiorly and to gently displace the bladder posteriorly.

Incision in the Endopelvic Fascia

The fibroadipose tissue covering the prostate is carefully dissected away to expose the pelvic fascia, puboprostatic ligaments, and superficial branch of the dorsal vein.

The endopelvic fascia is entered where it reflects over the pelvic sidewall, well away from its attachments to the bladder and prostate (Fig. 155.7). The point of incision is where the fascia is transparent, revealing the underlying levator ani musculature. Incision more medially can lead to entry into the lateral venous plexus of Santorini running alongside the prostate, resulting in persistent venous bleeding. Beneath this venous complex lie the prostatic arteries and the branches of the pelvic plexus that course toward the prostate, urethra, and corpora cavernosa.

FIG. 155.7 Incision in the endopelvic fascia and division of the puboprostatic ligaments. The incision in the endopelvic fascia is made at the juncture with the pelvic sidewall, well away from the prostate and bladder. Anteriorly, near the puboprostatic ligaments, small arterial and venous branches from the internal pudendal vessels have been clipped and divided. The puboprostatic ligaments are divided superficially far enough down to expose the juncture between the apex of the prostate and the anterior surface of the dorsal vein complex. However, the pubourethral component of the complex is intact to preserve anterior fixation of the striated sphincter to the pubis. *a.,* artery; *v.,* vein. (© Brady Urological Institute.)

The incision in the endopelvic fascia is then carefully extended in an anteromedial direction toward the puboprostatic ligaments. This allows the surgeon to palpate the lateral surface of the prostate. **At this point, small arterial and venous branches from the pudendal vessels are typically encountered that perforate the pelvic musculature to supply the prostate. These vessels should be ligated with clips to avoid coagulation injury to the pudendal artery and nerve, which are located just deep to this muscle as they travel along the pubic ramus.**

Division of the Puboprostatic Ligaments

The fibrofatty tissue covering the superficial branch of the dorsal vein and puboprostatic ligaments is gently teased away to prepare for division of the ligaments without injury to the superficial branch of the dorsal vein. After the superficial branch has been dissected away from the medial edge of the ligaments, it is coagulated and divided. After all fibrofatty tissue has been removed, a sponge stick is used to gently displace the prostate posteriorly, and scissors are used to divide each ligament (see Fig. 155.7).

The dissection should continue down far enough to expose the juncture between the apex of the prostate and the anterior surface of the dorsal vein complex at the point where it will be divided. The pubourethral component of the complex should be spared to preserve the anterior fixation of the striated urethral sphincter to the pubis (Burnett and Mostwin, 1998).

Preservation of Accessory Pudendal Arteries

Arterial insufficiency is a factor contributing to erectile dysfunction in patients after nerve-sparing RRP. One source for this insufficiency may arise from accessory pudendal arteries that travel over the anterolateral surface of the prostate. These arteries have been found in 70% of cadaveric dissections and 7% of patients by selective internal pudendal angiography. Large visible accessory pudendal arteries are present in 4% of men (Rogers et al., 2004).

Because release of accessory arteries may be associated with significant blood loss necessitating prompt ligation and division of the dorsal vein complex, it is useful to have the contralateral dissection completed before accessory vessels are released. For this reason, when these vessels appear to be prominent and are present unilaterally, the endopelvic fascia and puboprostatic ligament on the contralateral side should be divided first. The surgical technique for preservation of the arteries begins with division of the endopelvic fascia lateral to the vessels and division of the puboprostatic ligament (the vessels are beneath the puboprostatic ligament) (Rogers et al., 2004). Next, a vessel loop is used to elevate the artery; then with sharp dissection and a right-angled clamp, the accessory artery is released from its investing fascia (Fig. 155.8). As the dissection proceeds, venous tributaries are divided. At times, there may be substantial blood loss from the venous complex over the prostate; hemostasis, however, is usually easily obtained with a 4-0 running absorbable suture. The dissection must extend caudally beyond the site at which the dorsal vein complex will be divided.

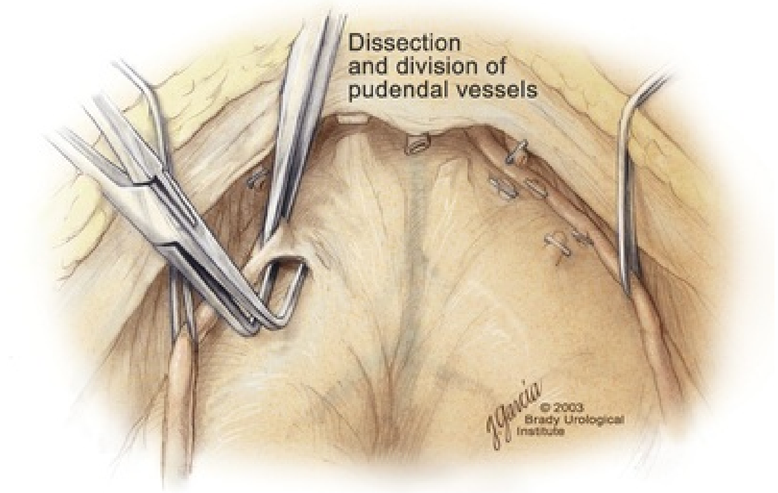

FIG. 155.8 Preservation of bilateral large accessory pudendal arteries. The anterior prostatic fascia is elevated with a right-angled clamp to facilitate release of the accessory pudendal vessels. (© Brady Urological Institute.)

Ligation and Division of the Dorsal Vein Complex

The goal is to divide the complex with minimal blood loss while avoiding damage to the striated sphincter and inadvertent entry into the anterior apex of the prostate. This can be accomplished with several approaches. Today we typically utilize an Endo GIA stapler (Medtronic, Minneapolis, MN) with a vascular load. After the apex is dissected, a Babcock clamp is used to bunch the two edges of the endopelvic fascia. Then the Endo GIA stapler is advanced over the dorsal vein approximately 4 cm and the GIA is then engaged, which will nicely delineate the apical anatomy. Next, the Foley catheter is manipulated; it should be moved in and out to ensure that the GIA stapler is not compressing the urethra. If the catheter moves freely, then the staples can be deployed. Over the past 4 years, Partin/Schaeffer have stapled approximately 800 dorsal vein complexes and have not “caught” the urethra in the GIA staple line. After deployment, the device is removed with nice delineation of apical anatomy with minimal to no blood loss. If a small amount of dorsal vein remains, a 3-0 Monocryl suture can be placed to control the residual vein. Once this is accomplished, the surgeon can progress to the urethral dissection.

This approach has several advantages. First, we estimate that there is substantially less blood loss (between 200 and 400 mL less) compared with more traditional ligation approaches. Second, a reduced amount of traction is needed to complete dorsal vein complex control. We believe this minimizes stretch injury to the NVBs and striated sphincter. Lastly, the design of the GIA stapler leaves three rows of staples on each side of the divided tissue. This provides excellent hemostasis of both the proximal and distal dorsal vein complex, and on the apical (prostate) side, the tissue contained in these staples provides ample coverage of the apex of the prostate, which can help with margins around anterior apical tumors.

A second, more traditional approach utilizes suture ligation. With use of a sponge stick to push the prostate posteriorly, a 3-0 Monocryl suture is passed through the dorsal vein complex just distal to the apex of the prostate (Fig. 155.9). In placing this stitch, the surgeon should face the head of the table, holding the needle driver against the pubis perpendicular to the patient. Next, the needle is reversed in the needle holder, and the same suture is placed through the perichondrium of the pubic symphysis (Fig. 155.10). Once this horizontal mattress suture is tied, three important goals are accomplished: (1) control of much of the venous bleeding without a “bunching” effect—this flat surface is much easier to divide; (2) recapitulation of the puboprostatic ligaments to provide additional anterior support of the striated sphincter; and (3) fixation of the dorsal vein complex anteriorly. This enables the surgeon to visualize the plane on the anterior apex of the prostate during division of the dorsal vein complex. The suture is not cut; it will be used once the dorsal vein is divided to oversew bleeders. Next, a Babcock clamp is used to bunch the two edges of the endopelvic fascia. A figure-of-eight 2-0 Caprosyn suture is then placed through this bunched tissue on the anterior surface of the prostate near the bladder neck. This reduces bleeding from the proximal dorsal veins, which can be excessive in some patients who have incompetent venous valves (Fig. 155.11).

FIG. 155.10 Next, the needle is reversed in the needle holder, and the same suture is passed through the perichondrium of the pubic symphysis. This maneuver is repeated to form a figure-of-eight horizontal mattress suture, which is then tied. (© Brady Urological Institute.)

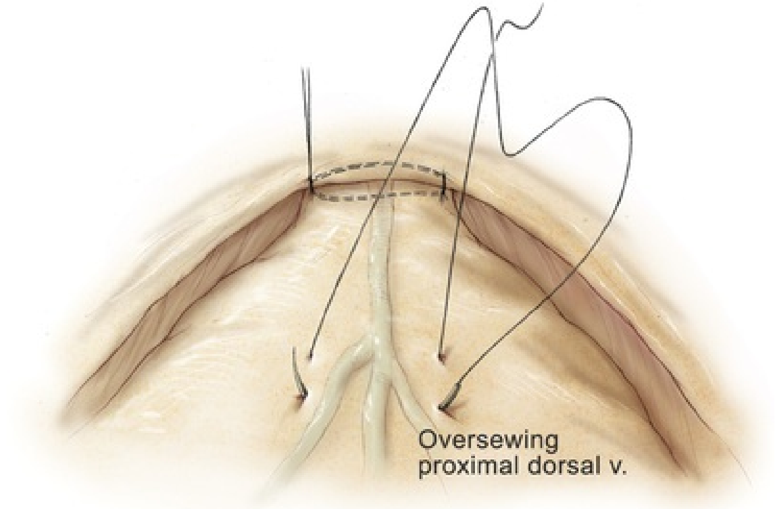

FIG. 155.11 A figure-of-eight 2-0 absorbable suture is placed on the anterior surface of the prostate to reduce bleeding from the proximal dorsal venous complex. *v.,* vein. (© Brady Urological Institute.)

Division of the Dorsal Vein Complex

Once the dorsal vein complex is ligated, one gently applies downward pressure on the anterior surface of the prostate with a sponge stick and a Metzenbaum scissors, or a No. 15 blade, is used to divide the complex. This is usually started on the left edge of the complex, where the junction with the apex of the prostate usually can be seen well (Fig. 155.12). Because the distal complex is fixed anteriorly, with downward pressure on the sponge stick, the exact plane between the juncture of the anterior surface of the prostate and the striated musculature can be visualized. Here loupes enable the surgeon to distinguish tissue textures and avoid positive margins. This is the most common site for positive surgical margins because it can be difficult to identify the anterior apical surface of the prostate. It also helps to rest the scissors on the anterior apex to find the correct plane.

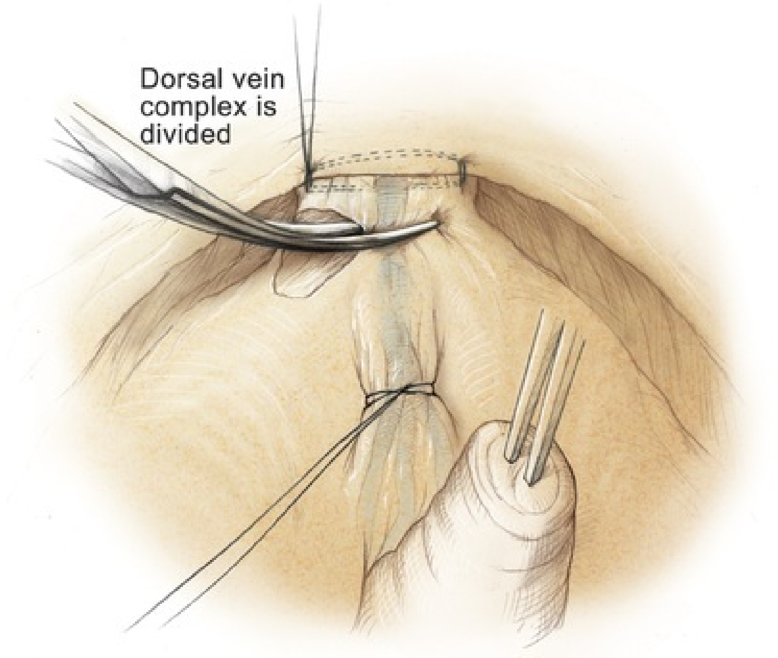

FIG. 155.12 With a sponge stick depressing the prostate posteriorly, the dorsal vein complex is divided beginning at the left edge. (© Brady Urological Institute.)

There is one important caveat in performing this maneuver. As the dissection proceeds posteriorly, **if the striated sphincter is divided too close to the apex of the prostate, there is risk that the NVB may be damaged**. **As the NVB approaches the apex of the prostate, it is often fixed medially beneath the striated sphincter by an apical vessel** (Walsh et al., 2000b). For this reason, the lateral edges of the sphincter along the urethra should be divided obliquely midway between the apex of the prostate and the pelvic floor. Absolute control of venous bleeding from the dorsal vein complex is mandatory so that the remainder of the procedure can be performed in a bloodless field. To achieve hemostasis, the 3-0 Monocryl suture on a ⅝ circle needle that was placed previously is used to oversew the superficial edges of the striated urethral sphincter–dorsal vein complex (Fig. 155.13). **In placing this running suture, the surgeon should face the head of the table, holding the needle driver against the pubis perpendicular to the patient.** If the needle driver is held loosely, the superficial edges of the complex can be easily approximated, forming a hood over the anterior urethra. Circumflex veins often are present at the posterior edge of the complex at the 5- and 7-o'clock positions; hemoclips often are used to control these bleeders. At the completion of this maneuver, hemostasis should be excellent.

Finally, to control back-bleeding from the anterior surface of the prostate, **the edges of the proximal dorsal vein complex on the anterior surface of the prostate are sewn together with the preplaced 2-0 suture** (Fig. 155.14). By pulling these edges together, tension on the prostatic fascia is evenly distributed, which can facilitate high release of the nerve bundles if the surgeon chooses to perform this maneuver (see detailed description later in this chapter).

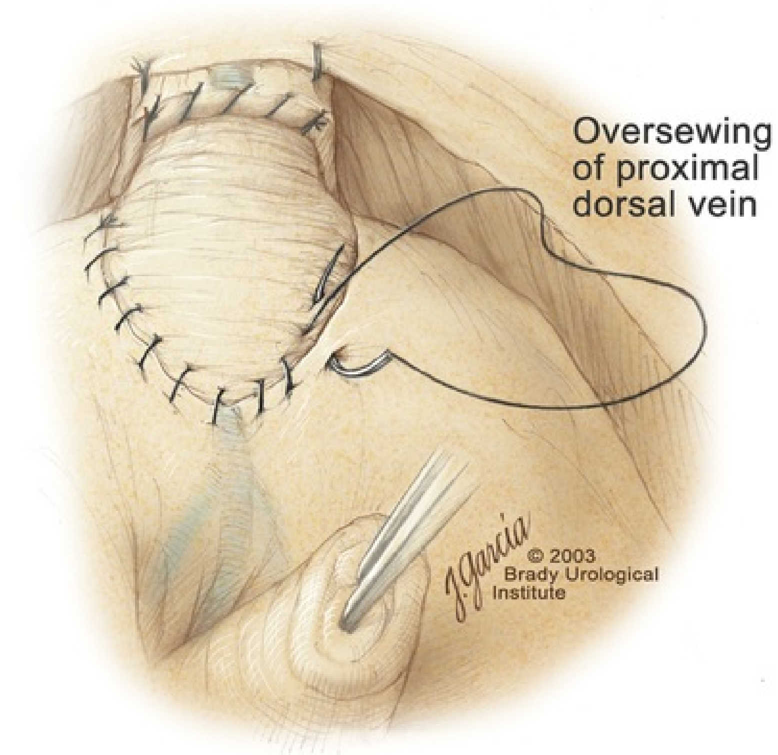

FIG. 155.14 The dorsal vein complex over the anterior surface of the prostate is oversewn in the shape of a *V* with a running 2-0 absorbable suture. (© Brady Urological Institute.)

Division of the Urethra and Placement of Urethral Sutures

The urethra should be divided first in performing a standard nerve release. If more aggressive nerve preservation is performed, the urethral incision should occur after nerve release (see later description). By gently displacing the prostate posteriorly with a sponge stick, the prostatourethral junction should be well visualized. The lateral bands of the striated musculature should be released as described earlier at their midpoint to free up as much of the urethra as possible. A right-angled clamp is then passed around the smooth musculature of the urethra near the apex of the prostate to ensure that the urethra is transected as close to the apex as possible (Fig. 155.15). This maneuver defines several key anatomic landmarks at the apex. First, it defines the posterior urethra from the posterior component of the striated sphincter. Second, if excellent hemostasis has been obtained, the association between the posterior striated sphincter and the nerve bundle should be able to be appreciated. With scissors, the anterior two-thirds of the urethra is divided with care to avoid damage to the Foley catheter. This provides excellent exposure for placement of six sutures in the distal urethral segment at the 1-, 3-, 5-, 7-, 9- and 11-o'clock positions. With 3-0 Monocryl on a ⅝ circle tapered needle, **the needle should incorporate just the urethral mucosa and submucosa but not the smooth muscle** (Fig. 155.16). As stated previously, the surgeon should face the head of the table to place these sutures and should hold the needle driver against the pubis, perpendicular to the patient. The first suture is placed in the mucosa and submucosa of the urethra at the 1- and 11-o'clock positions. By use of a 16-Fr catheter, the mucosa is easily identified. The smooth muscle should not be incorporated in this stitch because stitches in the smooth muscle delay the recovery of urinary control. If the urethral tissue appears flimsy, this suture should then be placed through the dorsal vein complex to improve tensile strength. Once the mucosa and submucosa have been elevated by these stitches, the remaining sutures are more easily placed. We place all sutures from the outside of the lumen to the inside; however, if sutures are more easily placed beginning on the luminal surface and then proceeding outside, a French eye needle can be used to place these sutures through the lumen of the bladder at the end of the case. The sutures are covered with towels to avoid inadvertent traction or displacement.

FIG. 155.16 The 3-0 Monocryl sutures are placed in the distal urethral mucosa and submucosa at the 12-, 2-, 10-, 7-, and 5-o'clock positions. The Foley catheter is then removed, the 6-o'clock suture is placed, and the posterior wall of the urethra is divided. *Post.,* posterior. (© Brady Urological Institute.)

The posterior band of the urethra is now divided to expose the posterior portion of the striated urethral sphincter complex (see Fig. 155.16). The posterior wall of the striated sphincter complex is composed of skeletal muscle and fibrous tissue. **Identification and precise division of this complex are important in (1) obtaining adequate margins of resection for apical lesions, (2) identifying the correct plane on the anterior wall of the rectum to ensure that all layers of Denonvilliers fascia are excised, (3) avoiding blunt trauma to the NVBs that are located immediately posteriorly, and (4) preserving urinary continence.**

To divide the posterior portion of the sphincter safely, a right-angled clamp is passed immediately beneath the left edge of this complex (Fig. 155.17). The clamp should pass midway between the apex of the prostate and the urethra. If it is passed too close to the apex of the prostate, it may damage the NVB. However, midway, the NVB is located more posteriorly and is beneath the right-angled clamp (Walsh et al., 2000b) (see Fig. 155.15).

FIG. 155.17 Division of the posterior component of the striated sphincter. A right-angled clamp is passed beneath the left edge of the striated sphincter midway between the apex of the prostate and urethra, at a site where the neurovascular bundles *(NVBs)* have fallen posteriorly. After the left edge of the complex is divided, a right-angled clamp is then passed along the right edge and the maneuver is repeated. *post.,* posterior. (© Brady Urological Institute.)

The left border of the complex is then divided with scissors. Next, the right-angled clamp is placed beneath the right edge of the complex, and the complex is divided. It is necessary to divide the complex from each side, because if division of the entire complex from one side is attempted, the contralateral NVB may be damaged. Finally, the central component of the complex is divided.

Identification and Preservation of the Nerve Bundle

Today, in most men who are candidates for surgery, it is safe to preserve both NVBs and rarely necessary to excise both of them (Walsh, 2001). With improved surgical techniques and the availability of phosphodiesterase type 5 (PDE5) inhibitors, most healthy potent men younger than 65 years of age should be potent after surgery. The NVB is outside the prostate between layers of lateral pelvic fascia (the levator fascia and prostatic fascia). If nerve sparing is performed correctly, the prostatic fascia must remain on the prostate. This is called an *interfascial* dissection. Furthermore, when cancer extends through the capsule, it rarely penetrates more than 1 to 2 mm, and this much tissue is often present even when the NVB is preserved (Hernandez et al., 2005). As Costello et al. (2004) have shown, the cavernous branches are positioned posterior to the capsular vessels, and the nerves immediately adjacent to the prostatic capsule are nerves going into the prostate, not the cavernous nerves.

To avoid bleeding from the capsular arteries and veins, some surgeons dissect beneath the prostatic fascia. This is called an *intrafascial* dissection. Because this plane is directly on the prostatic parenchyma, the risk for positive surgical margins is high. For this reason, this approach should never be used. Many well-meaning surgeons believe that if they excise the NVB, they can avoid a positive surgical margin. Unfortunately, this is not the case because the NVB is not the most common site for positive margins. Rather, the most common site is the apex, followed by posterior and then posterolateral sites. In 22%, the positive margins are multiple. In multiple studies, it has been demonstrated that the rate of positive margins in nerve-sparing and non–nerve-sparing procedures is the same (Ward et al., 2004). In Walsh's hands, the NVBs are preserved bilaterally in 87% of patients; one NVB is excised in 13%. This has resulted in an overall rate of positive surgical margins of approximately 5% (Epstein, 2001). The NVBs are rarely, if ever, excised bilaterally. We have always thought that if there is capsular penetration bilaterally to the point at which it is necessary to excise both NVBs, the patient most likely has distant dissemination and is not curable. Between 1986 and 1999, only seven potent men had both NVBs excised. Four were not cured because they had positive lymph nodes, positive seminal vesicles, or positive surgical margins elsewhere. In the three other patients, it was not necessary to excise both NVBs because there was no capsular penetration on one side.

How is the decision made as to when and where to excise the NVB? Preoperatively, no definite decision is made. Consideration is given to the status of sexual function, but in impotent patients, we do not always excise the NVBs because there is evidence that the bundles provide both somatic and autonomic innervation to the continence mechanism and that patients who undergo excision of both NVBs have more incontinence than do patients in whom the NVBs are preserved (Nelson et al., 2003). Consideration is also given to other important factors such as the presence of a *palpable apical lesion* and a high probability of capsular penetration based on the Partin tables (Partin et al., 1997, 2001). **However, no final decision is made until the time of surgery. When the endopelvic fascia is opened, if induration is palpable in the lateral pelvic fascia, the NVB on that side is widely excised. If there is no induration but the NVB appears to be fixed to the prostate at the time it is being released, it is also excised. However, the final decision about preservation or wide excision of the NVB does not need to be made until the prostate is removed. If there appears to be inadequate tissue over the**

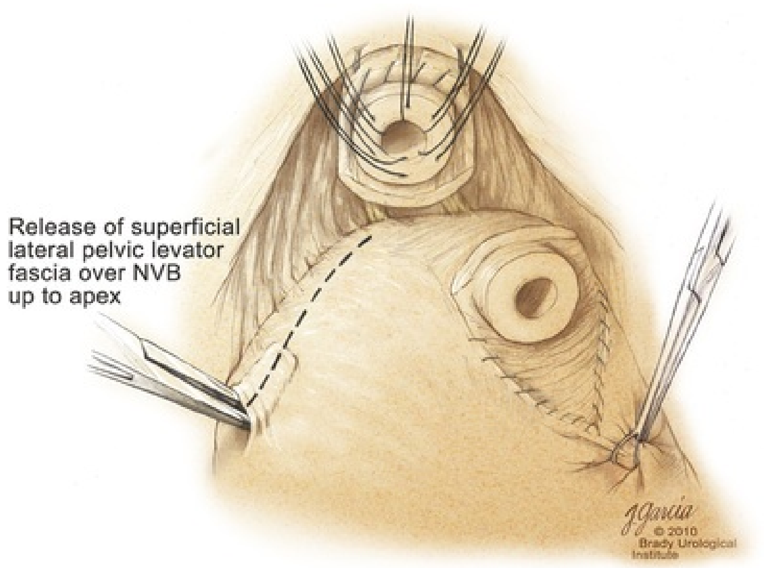
posterolateral surface after the prostate has been removed, the NVB can then be widely excised.

Identification of the Neurovascular Bundle

This is where the tactile sensation provided by open surgery is so important. If induration is palpable in the lateral pelvic fascia, the bundle should be excised. Also, in gently releasing the bundle with a right-angled clamp, if the bundle is fixed to the prostate, it should not be preserved. When the NVB is released, there should be no upward traction on the prostate. Rather, the prostate should be rolled from side to side. Also, the prostate is softer with the catheter out, and it appears easier to identify the correct plane for release of the NVB.

Standard Preservation of the Neurovascular Bundles

Standard nerve release begins after incision of the urethra, placement of urethral sutures, and release of the posterior striated sphincter. Recall that the lateral pelvic fascia is composed of two layers: the levator fascia and the prostatic fascia. The NVB travels between these two layers (see Figs. 155.4B and 155.5). With a right-angled clamp, the superficial layers of levator pelvic fascia are released. The use of loupes is helpful during this maneuver to ensure that the prostatic fascia has not been violated. The magnification also facilitates a more gentle dissection with less traction on the NVB. **A Babcock clamp or sponge stick is used during release of the NVB to manipulate the prostate. The clamp facilitates gentle elevation of the prostate during the release and can result in less traction on the NVB because the prostate is released from the bundle rather than the bundle being released from the prostate.** This dissection should begin at the bladder neck, where the fascia forms a thick band (Fig. 155.18). When this band is divided, the prostate immediately becomes more mobile. The superficial fascia should be released from the bladder neck to the apex. This maneuver releases the bundle laterally, thus making it easier to perform the next step, in which the bundle is released posteriorly at the apex.



Release of superficial lateral pelvic levator fascia over NVB up to apex

FIG. 155.18 The lateral surface of the prostate is exposed by displacing the prostate on its side with use of a Babcock clamp. A right-angled clamp is then inserted under the superficial layer of the levator fascia, beginning at the bladder neck and continuing all the way out to the apex. *NVB,* neurovascular bundle. (© Brady Urological Institute.)

Once the superficial fascia has been released, the location of the NVB can be identified by the presence of a subtle “groove” on the posterolateral edge of the prostate (Fig. 155.19). **By tracing this groove to the apex of the prostate, one can determine where the NVB begins to travel caudally and laterally away from the prostatic apex toward the urethra. Once the medial border of the NVB has been identified at the apex, the dissection in the midline can be safely carried posteriorly toward the rectum.**

FIG. 155.19 Once the levator fascia has been released, the neurovascular bundle *(NVB)* can be located by the presence of a subtle "groove" on the posterolateral edge of the prostate. This groove should be traced out to the apex of the prostate, and once the medial border has been identified, the dissection in the midline can be pursued, dividing residual layers of Denonvilliers fascia down to the rectum. (© Brady Urological Institute.)

The plane between the rectum and prostate having been developed in the midline, it is then possible to release the NVB from the prostate, beginning at the apex and moving toward the base, elevating and displacing the prostate over on its side. **Beginning on the rectal surface, the bundle is released from the prostate by spreading a right-angled clamp gently.** At the apex, there are often prominent apical vessels (Fig. 155.20). Because the prostate has been elevated on its side across the midline, this distorts the direction of the NVB by kinking it (see Fig. 155.20). If this artifact is not recognized, the NVB can be inadvertently transected. These vessels should be clipped and divided. Once the dissection has been initiated at the apex, it should proceed to the midpoint of the prostate. Because the superficial layers of the levator fascia have already been released, this dissection often proceeds easily. Furthermore, in using this plane, the Denonvilliers fascia and prostatic fascia remain on the prostate; only the residual fragments of the levator fascia are released from the prostate laterally. At this point in the procedure, the bundle should be released to the seminal vesicle (Fig. 155.21).

FIG. 155.21 The neurovascular bundle (NVB) has been released to just above the seminal vesicle. (© Brady Urological Institute.)

The vascular branches to the NVBs are best controlled by small hemoclips placed parallel to the bundle. Thermal energy of any form (unipolar, bipolar, or Harmonic scissors) should never be used on the NVB or its branches (Ong et al., 2004). Usually it is not necessary to clip the prostatic side of these tiny vessels; fine scissors should be used to divide them. The number of arterial and venous branches is extremely variable. By starting at the apex, however, one can easily identify them prospectively. If the fixation of the bundle to the prostate cannot be explained by vascular branches, the NVB should be excised. The surgeon should be aware that the bundle may travel more anteriorly in some patients. In these patients, one can confuse the groove with the potential space between the prostate and rectum. This is another good reason to release the bundle at the apex first. In addition, some patients have many veins on the lateral surface of the prostate that anastomose between the Santorini plexus anteriorly and the NVB posteriorly. The apical approach to the bundle facilitates management of this condition as well.

Furthermore, to make certain the Denonvilliers fascia is maintained on the prostate, the NVBs should be released by dissecting from the rectal surface anteriorly. Using the principles described earlier, positive surgical margins in patients with organ-confined disease that are caused by inadvertently cutting into the prostate are rare. Also, because the NVB is more mobile, it is easier to interrogate the surgical field with tactile sensation and magnification to find the correct plane. For this reason, even in patients with extraprostatic extension in the region of the NVB, it is possible to partially excise the bundle, preserve potency, and obtain negative margins of excision (Hernandez et al., 2005).

To avoid traction on the NVB, this dissection should continue cephalad to the level of the seminal vesicles (Masterson et al., 2008). At this point, the surgeon should look for a prominent arterial branch traveling from the NVB over the seminal vesicles to supply the base of the prostate (Fig. 155.22). This posterior vessel should be ligated on each side and divided. In doing so, the NVBs are no longer tethered to the prostate and fall posteriorly.

FIG. 155.22 Posterior dissection. The attachment of Denonvilliers fascia to the rectum is released, maintaining all layers of Denonvilliers fascia over the posterior surface of the prostate and seminal vesicles. Prominent branches from the neurovascular bundle *(NVB)* to the posterior surface of the prostate are identified at the posterolateral angle of the rectum. By dividing these posterior branches, the NVB is free to fall away from the prostate posteriorly. *Post.,* posterior. (© Brady Urological Institute.)

High Anterior Release of the Neurovascular Bundles at the Apex

The purpose of this approach is to speed up the recovery of sexual function and continence by reducing traction on the branches of the nerves to the cavernous bodies and striated sphincter or to avoid inadvertent transection of the small branches that travel anteriorly (Costello et al., 2004; Horninger et al., 2005; Menon et al., 2005; Montorsi et al., 2005; Takenaka et al., 2004, 2005)**. However, because there is less soft tissue at the apex, the risk for positive surgical margins could be increased by this approach. We select candidates for this approach using parameters that identify patients with a low risk for extraprostatic extension in the region of the NVB** (Tsuzuki et al., 2005). Tsuzuki et al. (2005) defined preoperative parameters to identify patients with a higher likelihood of extraprostatic extension in the region of the NVB. If patients have two or more of the following criteria, the risk for extraprostatic extension in the region of the NVB on that side is greater than 10%: prostate-specific antigen (PSA) level above 10 ng/mL, Gleason score higher than 6, average percentage of biopsy core on the side involved greater than 20%, percentage of cores with tumor on that side greater than 33%, or an abnormal finding on digital rectal examination.

The procedure begins after ligation of the dorsal venous complex and before incision of the urethra. Once total hemostasis is obtained, the levator fascia over the anterior apex of the prostate is incised and the incision is extended distally along the lateral edge of the apex of the prostate, preserving the underlying prostatic fascia (Fig. 155.23). The prostatic fascia is the glistening white fascia immediately below the veins that travel along the lateral surface of the prostate. **To identify the correct plane and avoid inadvertent incision into the prostate, it is essential to have excellent visualization and magnification.** In many patients, these venous tributaries must be divided and controlled. Cautery should not be used. Instead, hemostasis should be achieved by use of small hemoclips. As the dissection proceeds distally, the levator fascia should be released from the lateral shoulders of the prostate, with care taken not to enter the underlying prostatic fascia. **Because the recovery of sexual function at 12 months after unilateral high release was the same as with bilateral high release, we now routinely perform it on only one side, the side with the most favorable pathologic status.** Once the dissection has extended distally beyond the apex of the prostate, the NVB is exposed and released. Because the levator fascia has previously been released, prominent NVB usually can be visualized lateral to the urethra. At this point, as described by Masterson et al. (2008), the NVB is released from the lateral surface of the prostate to just above the seminal vesicles (Fig. 155.24). This approach avoids traction on the NVBs and makes the subsequent steps in preservation of the NVBs much easier (Fig. 155.25).

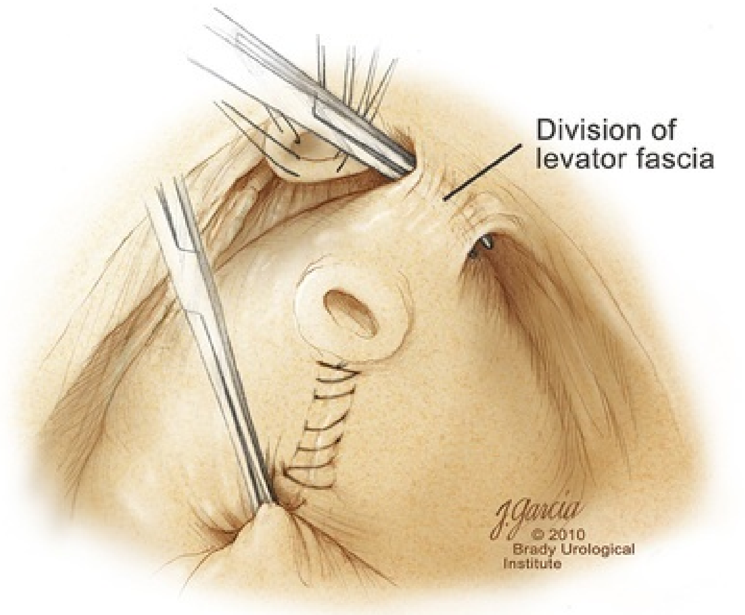

FIG. 155.25 If high release of the levator fascia was performed only unilaterally, after the posterior component of the striated sphincter has been divided, a right-angled clamp is inserted under the levator fascia on the side contralateral to the high release at the apex. This facilitates identification of the same dissection plane beneath the levator fascia as on the contralateral side without the need for approaching the plane by first dividing the levator fascia from the outside. (© Brady Urological Institute.)

Next, the urethra is transected and urethral sutures placed. The posterior component of the striated sphincter is transected. If high release of the levator fascia was performed only unilaterally, a right-angled clamp is inserted under the levator fascia at the apex on the side contralateral to the high release. This facilitates identification of the same dissection plane beneath the levator fascia as on the contralateral side without the need for approaching the plane by first dividing the levator fascia from the outside (see Fig. 155.25).

Wide Excision of the Neurovascular Bundles

Before excision of the NVB unilaterally, the contralateral NVB should be freed from the prostate, starting at the apex. This avoids traction injury, which can occur during wide excision of the contralateral bundle. The NVB to be excised is identified at the apex, and a right-angled clamp is passed from medial to lateral, immediately on the anterior surface of the rectum (Fig. 155.26). The bundle is divided without ligation in an effort to excise as much soft tissue as possible. Later, if bleeding is troublesome, the distal end can be clipped. The dissection is continued by dividing the fascia on the lateral surface of the rectum from the apex to the base so that the NVB and abundant fascial tissue are included in the specimen. This procedure is performed under direct vision, with the dissection terminating at the tip of the seminal vesicle, where the NVB is ligated and divided. In this way, the NVB and the lateral pelvic fascia are excised under direct vision in a more complete way than was previously possible (Fig. 155.27).

FIG. 155.26 Wide excision of the neurovascular bundle *(NVB).* Once the contralateral NVB has been released and residual attachments of the rectum to the prostate at the apex are freed, a right-angled clamp is then passed directly on the anterior surface of the rectum from the midline laterally. If the right-angled clamp is passed lateral to medial, a rectal injury is more likely to occur. *ant.,* anterior. (© Brady Urological Institute.)

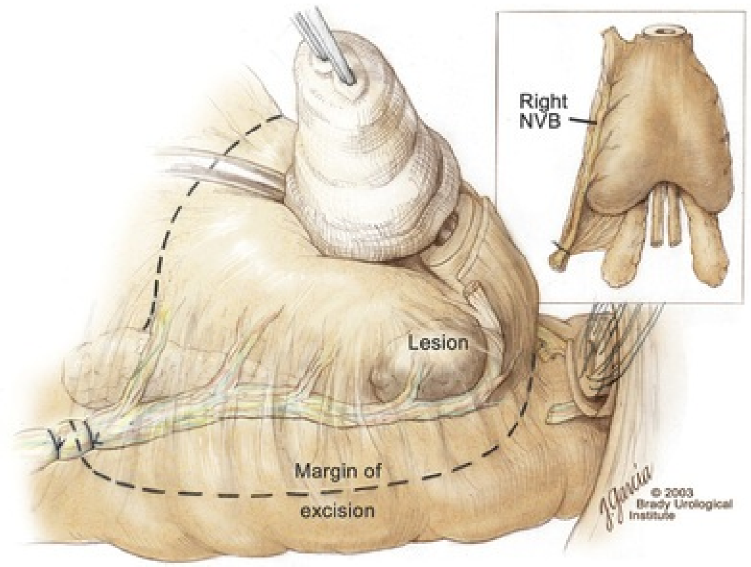

FIG. 155.27 Extent of the division of the neurovascular bundle *(NVB)* from the apex laterally to the tip of the seminal vesicle, where the NVB is ligated. This provides excellent soft tissue covering the primary lesion. (© Brady Urological Institute.)

Posterior Dissection and Division of the Lateral Pedicles

Once the NVBs have been either preserved at the apex or widely excised and the prostate has been mobilized to the level of the seminal vesicles, the catheter is replaced and, with light upward traction on the catheter, the attachment between the rectum and Denonvilliers fascia is divided in the midline posteriorly (Fig. 155.28). Because the NVBs have been freed up, traction can be applied to the catheter to gain exposure to the base of the prostate and seminal vesicles. However, to improve exposure, the sponge stick should never be placed on the prostate itself as it may displace tissue, producing a false-positive margin. Instead, the sponge stick should be placed on the catheter. In developing this plane, all layers of Denonvilliers fascia should be left covering the seminal vesicles.

FIG. 155.28 Lateral view demonstrating the location of the neurovascular bundle *(NVB)* after ligation of the posterior branch to the prostate. The site for division of the lateral pedicle is indicated. The lateral pedicle is thick and should be divided in layers: *1,* superficially; *2,* in the middle; and then *3,* deep next to the seminal vesicle. Trying to divide this thick pedicle all at once risks cutting into the overlying prostate. (© Brady Urological Institute.)

At this point, the lateral pedicle can be divided safely on the lateral surface of the seminal vesicles without injury to the NVB (see Fig. 155.28)**. The lateral pedicles are thick, and therefore need to be divided in a sequential way: superficial, middle, deep (next to the seminal vesicles). If one tries to divide them all at once, there is a risk for cutting into the overlying prostate.**

Obvious arterial bleeders are simply controlled with hemoclips. With this approach, one can leave more soft tissue on the prostate and protect the NVBs from injury. The dissection proceeds superiorly onto the anterolateral surface of the junction between the bladder and the prostate. Finally, Denonvilliers fascia is divided over the tips of seminal vesicles to facilitate removal. At this point, many surgeons elect to divide the vasa deferentia and free up the seminal vesicles.

Division of the Bladder Neck and Excision of the Seminal Vesicles

The prostate has now been mobilized almost completely. The bladder neck is incised anteriorly at the prostatovesicular junction (Fig. 155.29). The incision is carried down to the mucosa, the mucosa is incised, the Foley balloon is deflated, and the two ends of the catheter are clamped together to provide traction. As the incision in the bladder neck is widened, branches running from the inferior vesical pedicle to the prostate are noted at 5-o'clock and 7-o'clock positions (Fig. 155.30). **After these pedicles are divided, it should be possible to visualize the plane between the anterior surface of the seminal vesicles and the posterior wall of the bladder. By scissor dissection hugging the anterior surface of the seminal vesicles, the posterior bladder neck can be divided safely while observing the location of the ureteric orifices** (Fig. 155.31).

FIG. 155.31 The plane between the anterior wall of the seminal vesicles

and the posterior wall of the bladder neck for division of the posterior bladder wall. (© Brady Urological Institute.)

After the posterior bladder wall is divided, the bladder neck is retracted with an Allis clamp, and the vasa deferentia are ligated with hemoclips and divided. The seminal vesicles are dissected free from surrounding structures (Fig. 155.32). Recall that the pelvic plexus is located on the lateral surface of the seminal vesicles. **To avoid injury to the pelvic plexus, the surgeon should perform this dissection with great care, especially laterally, and direct vision should identify the small arterial branches that travel to the seminal vesicles and stay close to the seminal vesicles when these small vessels are ligated with small clips.** As the tips of the seminal vesicles are freed, small arterial branches at the tip of each seminal vesicle should be identified, ligated, and divided. Any residual attachments of Denonvilliers fascia are then divided, and the specimen is removed. The specimen is inspected carefully to identify any areas where the margin of resection is uncertain. If there is any concern about the margin on the posterolateral surface of the prostate, the NVB on that side should be excised.

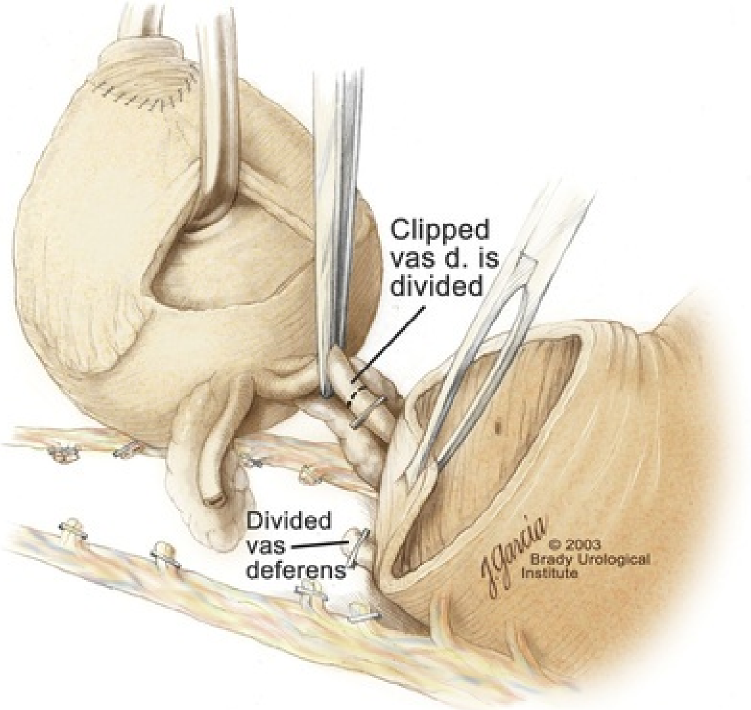

FIG. 155.32 Dissection of the vas deferens and seminal vesicles. The left vas deferens has been divided and ligated. The seminal vesicles are carefully dissected free from the pelvic plexus with direct visualization and

ligation of small arterial branches. *d.,* deferens. (© Brady Urological Institute.)

The operative site is inspected carefully for bleeding. **To avoid injury to the fine nerve fibers, small bleeding vessels near the NVB should not be cauterized.** Bleeding from these small vessels should be controlled with small hemoclips as the patient may develop a hematoma between the rectum and bladder. Inflammation surrounding the NVBs secondary to this hematoma may delay the return of sexual function (Walsh et al., 2000b). To avoid this adverse event, a small opening can be made in the peritoneum in the rectovesical cul-de-sac to facilitate decompression of a hematoma if it develops.

Bladder Neck Reconstruction and Anastomosis

The bladder neck is reconstructed with a running suture or interrupted 2-0 absorbable sutures to approximate full-thickness muscularis and mucosa, forming a tennis racquet closure (Fig. 155.33). At this point, it is useful to have previously injected indigo carmine to facilitate visualization of the ureteric orifices; ureteral catheters are not usually necessary. **By incorporating the mucosa in the closure, troublesome hematuria can be avoided.** The closure is initiated in the midline posteriorly and proceeds anteriorly until the bladder neck is narrowed to approximate the diameter of the urethra. Interrupted or running 4-0 absorbable sutures are used to advance the mucosa over the raw musculature of the bladder neck. In this way, a rosette of mucosa covers the bladder neck, facilitating a mucosa-to-mucosa urethrovesical anastomosis. The suture at the 6-o'clock position is left long to facilitate placement of the urethral sutures for the final anastomosis (see later description).

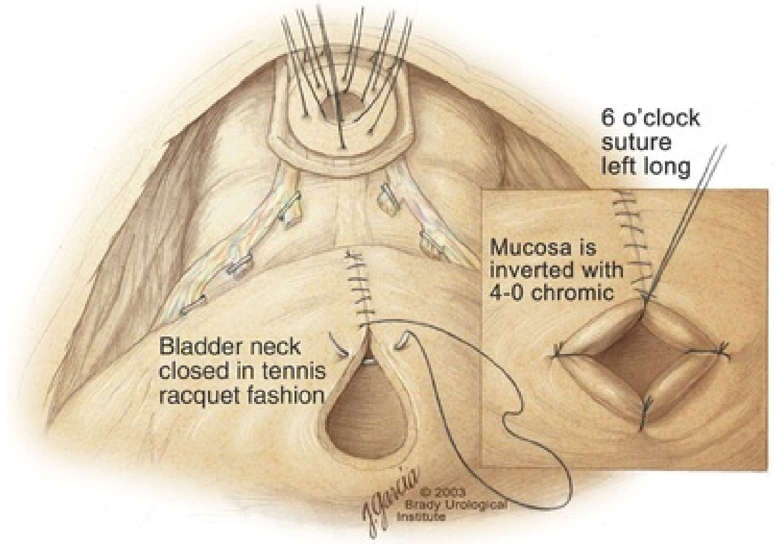

FIG. 155.33 Tennis racquet closure of the bladder neck with a running 2-0 absorbable suture incorporating all layers of the bladder wall. The bladder mucosa is then advanced over the raw bladder edges with interrupted 4-0 absorbable suture material to ensure a mucosa-to-mucosa anastomosis. The posterior midline suture (at the 6-o'clock position) is left long. (© Brady Urological Institute.)

At this point, the bladder neck can be anastomosed to the urethra, or buttressing sutures can be used to intussuscept the bladder neck (Walsh and Marschke, 2002)**. These sutures prevent the bladder neck from pulling open as the bladder fills.** The standard surgical technique described in this chapter emphasizes ample margins to ensure excellent cancer control, especially at the apex. Some surgeons preserve the puboprostatic ligaments and dissect beneath them closer to the apical prostate. Although this may preserve more of the striated sphincter, there is concern that it may lead to inadequate apical margins. The technique described herein may excise more striated musculature, and, consequently, it takes longer for some men to be pad-free. Parsons et al. (2004) found that with intussusception of the bladder neck, 80% of men are pad-free at 3 months and 98% at 1 year. A 2-0 Maxon suture is placed into the edges of the posterior bladder wall, where the bladder was previously attached to the prostate, approximately 2 cm from the reconstructed bladder neck (Fig. 155.34). If any hemoclips are in this area, they should be removed because they may be folded into the bladder neck, causing a bladder neck contracture. The suture is tied in the midline. The next suture is placed more anteriorly. Before this suture is placed, it is wise to release tension on the anterior bladder wall by loosening the malleable blade. This will aid in identifying the loose perivesical tissue that should be incorporated into this stitch. A second figure-of-eight 2-0 Maxon suture is placed approximately 2 cm lateral to the bladder neck on each side (Fig. 155.35). At this point, the bladder neck should protrude beneath the anterior hood of tissue that was created by the anterior stitch, resembling a turtle that is poking its head outside its shell. When the bladder neck is filled with saline, it should be competent with little leakage. After this test is completed, the bladder should be emptied completely by placing forceps through the bladder neck. The 6-o'clock suture should again be placed on traction to facilitate placement of the urethral sutures.

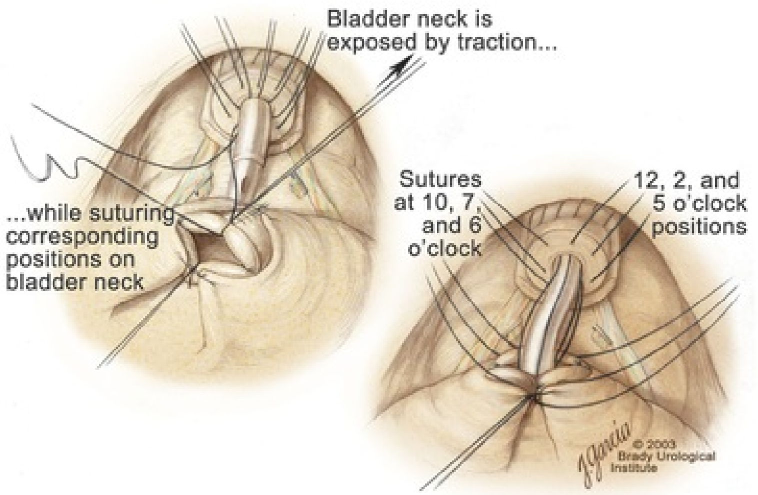
FIG. 155.35 Intussusception of the bladder neck. A second figure-of-eight 2-0 Maxon suture is placed anteriorly about 2 cm lateral to the bladder neck on either side and tied. (© Brady Urological Institute.)

The operative site is inspected carefully for bleeding. A new silicone Foley catheter (16-Fr, 5-mL balloon) is placed through the urethra into the pelvis. The six 3-0 Monocryl sutures that were previously placed in the distal urethra are now placed through the bladder neck in their corresponding positions from inside to outside (Fig. 155.36). Use of traction on the 4-0 suture that was placed at the 6-o'clock position to exteriorize the mucosa facilitates placement of the sutures. As mentioned earlier, a French eye needle is used for placement of the 12-, 2-, and 5-o'clock sutures. The catheter is irrigated free of clots, the balloon is tested, and the catheter is placed through the bladder neck and inflated with 15 mL of saline. The catheter is no longer placed on traction while the sutures are tied. Instead, a Babcock clamp, which is placed on the anterior bladder wall close to the reconstructed bladder neck, is used to hold the bladder in place while the sutures are tied (Fig. 155.37). This ensures excellent coaptation of the mucosa to mucosa and has markedly reduced the probability of bladder neck contractures.



Bladder neck is exposed by traction...

FIG. 155.37 A Babcock clamp is used to displace the reconstructed bladder neck into the pelvis and is held in place until all sutures are tied. This maneuver ensures that there is excellent coaptation of the reconstructed bladder neck to the urethra while the sutures are being tied. (© Brady Urological Institute.)

The anterior suture is tied initially. There should be no tension. Should tension arise, the bladder should be released from the peritoneum. The 2-, 5-

, 10-, 7-, and 6-o'clock sutures are tied sequentially. After all sutures are tied, the catheter is manipulated to make certain it is not caught in one of the sutures. The catheter is irrigated with saline to eliminate clots. After the operative site is irrigated vigorously with saline, a small suction drain is placed through the fascia (away from the midline) and directed into the operative site in the midline, between (not through) the rectus muscles. The incision is closed with a running No. 2 nylon suture and skin clips. The catheter is carefully taped to the thigh.

Postoperative Management

The postoperative recovery of men who undergo open RRP is often uneventful. The complication rates after open radical RRP have greatly improved over the past decade and were recently reviewed (Dasgupta and Kirby, 2009). A summary of the findings showed a marked decrease in length of stay (now averaging 1.7 days), lower urine leak rates (0.17%), lower need for transfusion (0.13%), lower postoperative ileus rate (0.6%), and a lower re-exploration rate for hemorrhage (0.08%).

Traditionally, men ambulate the evening of the procedure and are discharged on postoperative day 1 or 2. Pain control can be achieved by either intravenous patient-controlled analgesia with Dilaudid, fentanyl, or morphine on the night of surgery or with ketorolac. We use ketorolac in an effort to decrease the need for narcotics after surgery. Men with normal renal function (preoperative creatinine <1.2 mg/dL), no excess blood loss during the procedure (estimated blood loss <1500 mL), and no history of uncontrolled diabetes or postoperative hematuria receive a dose of intravenous ketorolac tromethamine, a nonsteroidal anti-inflammatory drug (NSAID), either before transfer to the recovery room or the morning after surgery. Recently, intravenous acetaminophen also has been administered to men for postoperative pain control with similar results but at present is quite costly. **This combination of analgesic agents reduces postoperative ileus.** Patients are offered a clear liquid diet on the evening of surgery and a regular low-fat diet the next day. A single closed-suction drain is left in place until discharge or it produces less than 50 mL/day off of suction.

The urinary catheter is left in place for 7 to 10 days postoperatively and represents a source of significant bother (Lepor et al., 2001), limiting the return to activities and work (Sultan et al., 2006). Therefore the urinary catheter should be removed as soon as possible without compromising outcomes (e.g., urinary retention and bladder neck contracture). Most would agree that removing the urinary catheter in the presence of significant urine extravasation would be unwise. Although 80% of vesicourethral anastomoses exhibit no evidence of cystographic extravasation by the fourth postoperative day, removal of the urinary catheter at this time is not recommended because of the high rate of acute urinary retention (Patel and Lepor, 2003). Approximately 10% of men will exhibit moderate extravasation on postoperative cystography performed 1 week after surgery. Routinely performing cystography at 1 week allows “early” removal of the urinary catheter while also identifying the small subset of men who might benefit from longer bladder drainage. However, this requires patients to return to the hospital/clinic, exposes them to radiation, and incurs additional expense to the process. Alternatively, our experience has shown that the urinary catheter may be removed safely by patients in their own home after 10 days. Bladder spasms will generally spontaneously subside, and reassurance is often sufficient. In cases of severe bladder spasms, an oral anticholinergic agent (oral oxybutynin [Ditropan] 5 mg) or diazepam (oral Valium, 5 to 10 mg) may be administered.

Complications

RRP is well tolerated, with minimal morbidity and low mortality (0.2%). Complications can be divided into those occurring intraoperatively and those occurring postoperatively.

Intraoperative Complications

The most common intraoperative problem is hemorrhage, usually arising from venous structures. Venous injury often can be controlled temporarily with packing, exposure, and suture or surgical clip ligation. If this is not successful, fine (No. 5-0) cardiovascular sutures may be required. Hemorrhage also can occur during incision in the endopelvic fascia, during division of the puboprostatic ligaments, or during exposure of the apex of the prostate with transection of the dorsal vein complex. If one understands fully the anatomy of the dorsal vein complex, this bleeding is usually satisfactorily controlled once the dorsal vein has been divided and carefully suture ligated. **If there is troublesome bleeding from the dorsal vein complex at any point, the surgeon should completely divide the dorsal vein complex over the urethra and oversew the end. This is the single best means to control bleeding from the dorsal vein complex.** While obtaining exposure for the prostatectomy, gentle traction must be put on the prostate. If the dorsal vein is not completely divided and ligated, this traction opens the partially transected veins and usually worsens the bleeding. With careful technique and a thorough knowledge of anatomy, the average blood loss during radical prostatectomy is 300 to 1000 mL routinely and rarely (<1%) requires intraoperative homologous blood transfusion. Because of these low transfusion rates, we no longer require the patients to donate/bank autologous blood before surgery. However, every case is required to undergo a type and screen sample before initiation of surgery.

Less common intraoperative complications include obturator nerve injury during pelvic lymph node dissection, rectal injury, and ureteral injury. If the obturator nerve is inadvertently severed, an attempt should be made at reanastomosis with fine nonabsorbable sutures. Rectal injury is an infrequent (<0.3%) but serious complication. Rectal injury occurs most often during apical dissection in attempting to develop the plane between the rectum and Denonvilliers fascia. When a rectal injury occurs, the prostatectomy should be completed, the bladder neck should be reconstructed, and hemostasis should be excellent. It is critical to attempt to interpose omentum between the rectal closure and the vesicourethral anastomosis to reduce the possibility of a rectourethral fistula. This maneuver can be accomplished simply by making a small opening in the peritoneum; finding the omentum and fashioning a slender, well-vascularized pedicle that will be long enough to reach the pelvic floor; dividing the peritoneum in the rectovesical cul-de-sac; and feeding the end of the omental pedicle through this opening. The anal sphincter is digitally dilated widely by an assistant, and the rectal injury is clearly delineated. With excellent visualization, the edges of the rectal wound are freshened and closed in two layers. The omental pedicle is immobilized over the repair with absorbable sutures, and the vesicourethral anastomosis is performed. The wound should be copiously irrigated with antibiotic solution, and the patient should be maintained for several days on broad-spectrum antibiotics for both aerobic and anaerobic bacteria. When this technique was used, all recovered without development of a wound infection, pelvic abscess, or rectourethral fistula (Borland and Walsh, 1992). However, if the patient has received prior radiotherapy (salvage prostatectomy), it is prudent to perform a diverting colostomy. Ureteral injury is also very rare and usually occurs secondary to inadvertent dissection within the layers of the trigone while attempting to identify the proper cleavage plane between the bladder and seminal vesicles. If this injury occurs, ureteral reimplantation should be undertaken.

Postoperative Complications

Life-threatening delayed hemorrhage is a rare complication of RRP. Significant bleeding after radical prostatectomy is defined as postoperative hemorrhage requiring the acute transfusion of blood to support blood pressure (Hedican and Walsh, 1994). Rarely a patient will require exploration for delayed bleeding, and most cases are managed expectantly. The mean blood product requirements for patients who were explored were comparable with those for patients managed conservatively, although total hospitalization was shorter in patients who underwent a secondary operation. In patients managed nonoperatively, the pelvic hematoma may drain through the urethrovesical anastomosis, resulting in symptomatic bladder neck contractures and long-term problems with urinary control. In this study, only 25% of men explored for delayed bleeding experienced prolonged mild incontinence (Hedican and Walsh, 1994). **These**

results suggest that patients requiring acute transfusions for severe hypotension after radical prostatectomy should be explored early to evacuate the pelvic hematoma in an effort to decrease the likelihood of bladder neck contracture and incontinence.

Thromboembolic Events

Deep venous thrombosis (DVT) with pulmonary embolism is a major cause of mortality after radical prostatectomy. A recent review of over 45,000 surgical prostate procedures completed in Sweden demonstrated that the highest rates were seen when pelvic lymph node dissection was performed as part of the procedure and that the highest likelihood occurred between 14 and 28 days after the procedure. This highlights the need for continued attention to risk as long as 4 weeks after the procedure. Measures to prevent this complication include careful positioning on the operating room table to avoid compression of the veins in the lower extremity, use of intermittent compression devices, and early ambulation. Mini-dose heparin or low-dose, low-molecular-weight heparin is used at some centers (but not at ours).

Most importantly, all patients should be repeatedly informed of the signs and symptoms of DVT and pulmonary embolism before discharge and should be instructed verbally and in writing to call immediately if they have any of the following symptoms: swelling or pain in the leg, especially in the calf; sudden chest pain that is worse on taking a deep breath; hemoptysis; shortness of breath; or the sudden onset of weakness or fainting. We have found that an informed patient is the best way to reduce the morbidity and mortality from thromboembolic events. When patients develop DVT or pulmonary embolism events, twice-daily subcutaneous administration of low-molecular-weight heparin without monitoring of clotting factors appears to be at least as effective and safe as an adjusted-dose, intravenous administration of unfractionated heparin (Büller et al., 2003).

Bladder Neck Contracture

Bladder neck contractures historically occur in 0.5% to 10% of patients after radical prostatectomy, and the rate has diminished dramatically over the past decade. They arise from inadequate coaptation of the mucosal surfaces. This may be a result of inadequate approximation at the time of surgery, urinary extravasation, or distraction of the bladder neck from a

hematoma. The diagnosis should be considered in any patient who complains of a poor urinary stream or in patients who have prolonged unexplained incontinence. If treatment with simple cystoscopic dilation fails, direct cold-knife incision of the bladder neck at 3-, 6-, and 9-o'clock followed by intermittent self-catheterization for a limited time usually corrects the problem. In patients with recalcitrant bladder neck contractures, the injection of triamcinolone acetonide (200 mg in 5 mL) at the bladder neck after cold-knife incision may be useful.

Urinary Incontinence

After radical prostatectomy, incontinence is usually secondary to intrinsic sphincter deficiency. Kim et al. (2013) demonstrated in a Surveillance, Epidemiology, and End Results (SEER) Program population that only 6% of over 16,000 men older than 65 years of age had undergone an “incontinence procedure” within the first 2 years after prostatectomy. In some men, the striated sphincter may be poorly developed; in older men, it is thinner and contains more collagen (Burnett and Mostwin, 1998; Strasser et al., 1999). However, the predominant cause of this deficiency is injury during ligation and division of the dorsal vein complex. The smooth musculature of the urethra, which also contributes to continence, can be damaged by placement of large, deep sutures for the anastomosis or denervated by injury to the NVBs. Furthermore, the bladder neck must be supple, with a diameter that is not excessively large, because urinary continence can be hampered by the development of a bladder neck contracture or a wide bladder neck (Groutz et al., 2000; Horie et al., 1999). To avoid these complications, as outlined earlier, it is important to preserve the striated sphincter during the apical dissection, to avoid tension on the final anastomosis, to reconstruct the bladder neck so that the opening is small and supple, and to accomplish a precise mucosa-to-mucosa anastomosis. Many men have detrusor hypertrophy and decreased bladder compliance from preexisting bladder outlet obstruction. It takes these patients longer to achieve full urinary control. For this reason, it is important to avoid excessive traction on the bladder intraoperatively, which may aggravate this condition.

During their recovery, patients need constant encouragement and advice at regular intervals. Until urinary control has returned completely, patients are advised to reduce their fluid intake, avoid caffeinated beverages and alcohol, and stop α-adrenergic antagonists if they take them for the treatment of hypertension. Treatment with imipramine or α agonists in men who are not hypertensive can be helpful.

Erectile Dysfunction

Three factors are important in the recovery of erectile function after radical prostatectomy: age of the patient (younger than 65 years), status of potency preoperatively, and ability to intraoperatively preserve both NVBs. Walsh et al. (2000a) evaluated impotence by a validated questionnaire sent to an independent third party for review. In his hands, 86% of the patients were able to have unassisted intercourse with or without sildenafil citrate at 18 months. Although one-third of patients were taking sildenafil citrate, only 4% of men reported that they could not have intercourse without it. The important message for the patient is that the recovery of sexual function occurs gradually: 38% of Walsh's patients were potent at 3 months, 54% at 6 months, 73% at 12 months, and 86% at 18 months. The patient's age at the time of surgery also affects recovery of sexual function (Parsons et al., 2004).

High anterior release of the NVB as demonstrated in Video 155.2 is associated with significantly earlier recovery and return to baseline sexual function. In potent men undergoing high anterior release, 93% were potent 12 months after surgery, and 70% reported a return to their baseline erectile function. In men who preoperatively reported a frequency of intercourse more than once per week, 78% reported a return to their baseline sexual function at 12 months (Nielsen et al., 2008). Interestingly, this recovery and return to baseline function was noted in men who underwent either a unilateral or bilateral high release. This suggests that the improved sexual recovery associated with this technique is not likely caused by preservation of anterior branches of the cavernous nerves but rather by improved accuracy in the preservation of the nerves with less traction. **Other experienced surgeons also have noted improved recovery of sexual function using similar early nerve release techniques, providing further merit to this technical modification** (Masterson et al., 2008).

In patients who are medically cleared, PDE5 inhibitors augment sexual recovery after radical prostatectomy. Montorsi et al. (2008) reported on a multi-institutional randomized, double-blind study examining recovery of erectile function using either vardenafil “on demand,” nightly, or placebo for 9 months. At the end of the blinded treatment period, vardenafil on demand was of greater benefit than nightly treatment. In a similarly devised trial, Pavlovich et al. (2009)

noted no difference in recovery of sexual function in patients using either on-demand or nightly sildenafil, with a trend toward improved recovery in the on-demand arm. **Thus, on-demand dosing of PDE5 inhibitors appears to be the most effective method to aid in recovery of sexual function.**

Summary of Radical Retropubic Prostatectomy

A number of advances have been made in the diagnosis and treatment of localized prostate cancer. Today, more men are diagnosed with curable disease at a younger age. Men are also living longer; a man 65 to 70 years of age has a 50% chance of living for another 15 years. Open radical prostatectomy is an ideal form of treatment for patients who can be cured and who will live long enough to benefit from it. These are also the patients who will have the best quality of life postoperatively (Walsh, 2000).

Over the past decade, there has been increasing adoption of robotic-assisted laparoscopic radical prostatectomy. Some experts claim that the open approach is of only historical interest because of superior outcomes after the robotic approach. The primary advantage of the robotic approach is less blood loss. Even proponents of the robotic approach concede after 10 years there is no meaningful advantage of the robotic approach (Lavery et al., 2012). Despite public demand, the authors of this chapter continue to perform the open approach.

Key Points: Anatomic Radical Retropubic Prostatectomy

- There is no better way to cure cancer that is confined to the prostate than total surgical removal.
- The three goals of the surgeon, in order of importance, are cancer control, preservation of urinary control, and preservation of sexual function.
- Surgery is deferred for 6 to 8 weeks after needle biopsy of the prostate and 12 weeks after transurethral resection of the prostate.
- A fiberoptic headlight and 2.5- to 4.5-power loupes are most useful because much of the procedure is performed beneath the pubis in an area where visualization can be difficult. Magnification can enable the surgeon to exert less traction on the NVBs and more easily identify the correct plane of dissection.

- Regional anesthesia is associated with less blood loss and a lower frequency of pulmonary emboli.
- If the patient has a well-differentiated to moderately well-differentiated tumor (Gleason grade <8) and the lymph nodes are normal to palpation, frozen-section analysis is not performed.
- With the recent recognition that branches of the nerves innervating the striated sphincter and cavernous bodies may travel more anteriorly at the apex, an alternative technique involving high anterior release of the NVBs at the apex before division of the dorsal vein is described. This technique is associated with earlier recovery of sexual function.
- In most men who are candidates for surgery, it is safe to preserve both NVBs and rarely necessary to excise both of them, thus making cavernous nerve replacement or transplantation unnecessary in most cases.
- The tactile sensation provided by open surgery is very important. If induration is palpable in the lateral pelvic fascia, the bundle should be excised. In gently releasing the bundle with a right-angled clamp, if the bundle is fixed to the prostate, it should not be preserved. With the laparoscopic technique, tactile sensation is muted; with the robotic-assisted technique, it is absent.
- Patients requiring acute transfusions for hypotension after radical prostatectomy should be explored to evacuate the pelvic hematoma in an effort to decrease the likelihood of bladder neck contracture and incontinence.
- Thrombophlebitis with pulmonary embolism is the major cause of mortality after radical prostatectomy. Measures to prevent this complication include careful positioning on the operating room table to avoid compression of the veins in the lower extremity, the use of intermittent compression devices, and early ambulation.
- Complete excision of the seminal vesicle during radical prostatectomy is essential for cancer control.
- Open radical prostatectomy is an ideal form of treatment for patients who can be cured and who will live long enough to benefit from it.

Videos 155.3 to 155.11 demonstrate techniques related to this chapter.

Laparoscopic and Robotic-Assisted Laparoscopic Radical Prostatectomy and Pelvic Lymphadenectomy

---

Li-Ming Su MD, Brandon J. Otto MD, Anthony J. Costello FRACS, MD

Evolution of Minimally Invasive Laparoscopic Prostatectomy

In the late 1970s and early 1980s, several detailed anatomic studies performed in fetal and adult cadavers provided important insights into the periprostatic anatomy, especially that of the dorsal venous complex (DVC) (Reiner and Walsh, 1979), the neurovascular bundle (NVB) (Walsh and Donker, 1982), and the striated urethral sphincter (Oelrich, 1980). These observations provided a more anatomic approach to radical prostatectomy for prostate cancer, resulting in a significant reduction in operative morbidity. Subsequently, the anatomic, nerve-sparing open radical prostatectomy maintained a central role in the management of localized prostate cancer for more than two decades.

It was not until 1997 that an attempt at a less invasive approach to radical prostatectomy was explored. Schuessler et al. (1997) performed the first successful laparoscopic radical prostatectomy (LRP) in 1997. In their series of nine patients, operative duration was lengthy (8 to 11 hours), and the length of hospital stay was on average 7.3 days. Although the authors concluded that cure rates with LRP appeared comparable with those in open surgery, they could not define any significant advantages. As a result, LRP was not widely adopted in the field of urology.

Advances in task-specific surgical instrumentation, optics, digital video equipment, and computer and robotic technology opened a new frontier for minimally invasive laparoscopic prostatectomy. These advances led urologists to revisit LRP, spearheaded by two centers in France that reported on their techniques and early results (Abbou et al., 2000; Guillonneau and Vallancien, 2000). Their stepwise surgical approach to LRP proved to be both reproducible and teachable, although the learning curve remained challenging. Operative times were in a more acceptable 4- to 5-hour range, with reported overall positive margin rates of 15% to 28%. This work rekindled worldwide interest in LRP, and in the ensuing years, surgeons at a number of centers throughout the world acquired the skills and experience to perform this technique. However, advanced laparoscopic skills were necessary to perform a proficient LRP, especially for suturing of the vesicourethral anastomosis.

Computer-assisted surgical devices using mechanical robotic arms were adopted for use with radical prostatectomy in part because of their ability to aid the surgeon in performing the challenging task of laparoscopic suturing. One such device, the da Vinci Surgical System (Intuitive Surgical, Sunnyvale, CA) quickly became the dominant robotic surgical device in the field of urology. By incorporating sophisticated wristed technology at the terminal ends of the robotic instruments, this robotic system offered surgeons the ability to operate, dissect, and suture with the facility of a human wrist. In addition, the 10× magnified, three-dimensional image provided by the specialized stereo-endoscope lens and camera offered an unprecedented view of the operative field and periprostatic anatomy, far superior to the two-dimensional view of conventional laparoscopy. The first-generation robotic platform, originally launched in the United States in 2000, allowed surgeons to control three robotic arms simultaneously: two arms for robotic instrumentation and a third arm for control of the stereo-endoscope and camera. The second-generation da Vinci S system, made available in 2006, incorporated high-definition image capability with an additional fourth robotic arm for grasping and retraction. The third-generation da Vinci Si HD was released in 2009 and offered two separate surgeon consoles, allowing two surgeons to operate simultaneously and providing an opportunity for improved operative efficiency and training. Finally, the latest-generation robot, the da Vinci Xi HD, launched in 2014, allows for multi-quadrant surgery and simpler, single-quadrant surgery.

Since its introduction in the United States in 2000, robotic-assisted laparoscopic radical prostatectomy (RALRP) has rapidly grown in popularity with surgeons and patients alike. However, there are continued questions regarding the relative merits of RALRP versus open surgery with regard to oncologic and functional outcomes, weighed against the significant equipment expense and learning curve for the surgeon and surgical team. **Nevertheless, with rapid dissemination of robotic platforms into large tertiary referral centers and community hospitals, RALRP has become the dominant surgical approach for radical prostatectomy in the United States**.

This chapter highlights some of the surgical advances for both LRP and RALRP. Further, technical details for the surgical dissection and currently available data on oncologic and functional outcomes are presented with reference to comparative effectiveness with radical retropubic prostatectomy (RRP). Finally, the authors review the role of robotic salvage prostatectomy, laparoscopic pelvic lymph node dissection (PLND), and complications of minimally invasive prostatectomy.

Patient Selection

Indications and Contraindications

The indications for LRP and RALRP are identical to those for open surgery (i.e., patients whose cancer is suspected to be clinically localized). Patients should have a pathologically confirmed cancer clinically confined within the prostate (stage T1 or T2) or a cancer that extends beyond the margins of the prostate (T3) but still seems amenable to surgical extirpation with a wide resection. Based on the 2018 Clinically Localized Prostate Cancer: AUA/ASTRO/SUO guideline, radiographic staging with CT and bone scan is recommended only for patients with suspected locally advanced disease, Gleason score of 8 or greater, or prostate-specific antigen (PSA) level greater than 20 ng/mL (Sanda et al., 2018). Absolute contraindications to minimally invasive laparoscopic prostatectomy include uncorrectable bleeding diathesis and the inability to undergo general anesthesia because of severe cardiopulmonary compromise. Patients who have received neoadjuvant hormonal therapy or who have a history of prior complex lower abdominal and pelvic surgery such as partial colectomy or inguinal mesh herniorrhaphy pose a greater technical challenge because of distortion of normal anatomic landmarks and adhesions but are not an absolute contraindication to LRP and RALRP. In patients with a history of prior laparoscopic extraperitoneal mesh herniorrhaphy, a transperitoneal approach may be preferred over the extraperitoneal approach because dense adhesions in the retropubic space often make attempts at initial access to the space of Retzius challenging.

Morbidly obese patients pose additional challenges, even to experienced surgeons. These patients are more prone to positioning injuries such as compression nerve injuries, therefore extra care must be taken, and additional padding of pressure points is often required. Additionally, they are at an increased risk for potential respiratory compromise when placed in the steep Trendelenburg position, making communication with the anesthesia team key once they are positioned and pneumoperitoneum is established. Deep venous thrombosis risk may be increased in these patients, and consideration should be given to the use of pharmacologic prophylaxis in addition to the routine use of sequential compression devices and early ambulation. From a technical standpoint, the relatively limited working space and limitations of trocar size and instrumentation length can pose additional problems. Modifications that may help improve surgeon visualization and maneuverability in a morbidly obese patient include using extra-long trocars; placing trocars 1 to 2 cm more cephalad to improve the angle of approach to reduce instrument collision with the pubic symphysis; dividing the urachus at a more cephalad location to eliminate fat from the abdominal wall obscuring the field; and decreasing the pneumoperitoneum to 10 mm Hg with deeper insertion of trocars to allow instruments to reach the apex or the vesicourethral anastomosis (Ganapathi et al., 2017). In experienced hands, it is possible to obtain adequate operative, functional, and oncologic outcomes in morbidly obese patients (Abdul-Muhsin et al., 2014).

Patients with large prostate volumes (e.g., >80 g) often offer technical challenges to the surgeon. Larger prostates tend to fill most of the pelvic cavity making maneuverability of the prostate more difficult. Additionally, a concomitant median lobe can make division of the posterior bladder neck with respect to the nearby ureteral orifices more challenging and may require a more extensive bladder neck reconstruction. These patients may also have a wider DVC and wider and more vascular pedicles, and the neurovascular bundle may be displaced posteriorly making visualization more difficult (Ganapathi et al., 2017). Tips for dealing with these challenging situations are presented later in this chapter at the corresponding steps of the operation. Review of the preoperative transrectal ultrasound scan or imaging before surgery can alert one to the presence of a large prostate or a prostate with a median lobe, allowing the surgeon to better prepare for the operation. These patients can have longer operative times, more blood loss, and longer hospital stay than those with smaller glands; however, long-term urinary outcomes appear comparable (Levinson et al., 2008, 2009; Link et al., 2008).

Patients who have undergone a prior transurethral resection of the prostate (TURP) can also have more complex bladder neck anatomy. Identification of the ureteral orifices is imperative before beginning the posterior bladder neck dissection. The normal planes between the prostate and bladder may be altered making dissection more difficult. These cases are often difficult, and both oncologic and functional outcomes may be compromised (Gupta et al., 2011). Salvage surgery after failure of primary treatment (e.g., radiation, brachytherapy, cryotherapy, high-intensity focused ultrasonography) has been successfully reported in properly selected patients but should be approached with caution because of the attendant risks and complications related to periprostatic adhesions (Boris et al., 2009; Chauhan et al., 2011; Kaffenberger et al., 2013; Kaouk et al., 2008; Yuh et al., 2014). As a result of the effects of prior local radiotherapy or ablation, the tissue planes surrounding the prostate, and especially between the posterior prostate and anterior rectum, are often fibrotic and obliterated, increasing the risk for inadvertent entry into the rectum during salvage surgery. As a result, patients undergoing salvage prostatectomy need to undergo a full bowel preparation and be counseled on the potential risk for rectal injury and colonic diversion in addition to the higher incidence of impotence and incontinence compared with surgery in the primary setting. Further discussion regarding the nuances of salvage robotic prostatectomy can be found in the Surgical Technique section later in this chapter. **It is strongly advised that these more complex patient scenarios be avoided in a surgeon's early experience with LRP and RALRP; however, these patient features are not by themselves absolute contraindications for a minimally invasive approach to prostatectomy** (Brown et al., 2005b; Erdogru et al., 2005; Kaffenberger et al., 2013; Singh et al., 2005; Stolzenburg et al., 2005).

Use of Preoperative Multiparametric Magnetic Resonance Imaging

Multiparametric magnetic resonance imaging (mpMRI) of the prostate is increasingly being performed to assist with the diagnosis, staging, and management of prostate cancer. mpMRI has been shown to have high specificity (0.88) and low sensitivity (0.61) for staging of localized prostate cancer (de Rooij et al., 2016). However, mpMRI is often reader dependent, and having a dedicated reader can improve its ability to predict adverse pathology (Tay et al., 2016). **The addition of mpMRI to commonly used clinical risk classification tools seems to improve their ability to predict extracapsular extension** (Feng et al., 2015; Morlacco et al., 2017)**. This information may help improve both patient counseling and surgical planning.** Studies are beginning to suggest that the addition of preoperative mpMRI can help with nerve-sparing planning, allowing for a more tailored approach and reducing positive surgical margins with the use of improved planning or intraoperative frozen sections in areas of concern at the time of prostatectomy, even in high-risk patients (Radtke et al., 2015; Rud et al., 2015; Schiavina et al., 2018). It remains to be seen if preoperative mpMRI is necessary in all patients undergoing RALRP, but when available, it should be reviewed for surgical planning.

Instrumentation

Instrumentation required for LRP and RALRP depends on the chosen approach and model of da Vinci system being used (i.e., three- vs. four-arm robot) in the case of RALRP. Box 156.1 lists suggested instrumentation for LRP and RALRP. For LRP, the AESOP 3000 robotic arm (Intuitive Surgical) may be used to stabilize and control the laparoscopic lens and camera by handheld remote control, voice activation, or foot-pedal control. Alternatively, a surgical assistant can be used for this purpose. During RALRP, the use of the da Vinci S, Si, or Xi system allows the surgeon to control a total of four robotic arms, with one being the stereo-endoscope. The operation begins by using a 0-degree stereo-endoscope and controlling a grasping forceps in the left robotic arm (such as the Maryland curved bipolar forceps or plasma kinetic dissector) and the curved monopolar scissors in the right robotic arm. The fourth robotic arm controls the ProGrasp forceps (Intuitive Surgical), a large atraumatic blunt grasper for retraction and exposure of tissues. The surgeon then toggles between control of any two of the three working robotic arms at any given time to allow for greater autonomy and to achieve optimal exposure and dissection.

Box 156.1

Suggested Instrumentation for Laparoscopic and Robotic-Assisted Laparoscopic Radical Prostatectomy

Laparoscopic Radical Prostatectomy

- AESOP 3000 Robotic arm (Intuitive Surgical, Sunnyvale, CA) (optional)
- Monopolar electrocautery scissors
- Monopolar electrocautery hook device
- Bipolar forceps
- Ultrasonic shears
- Maryland dissector
- Laparoscopic needle drivers (two)
- Suction-irrigation device

- 10-mm, 0-degree and 30-degree laparoscope lens
- Veress needle
- 5-mm trocars (three)
- 12-mm trocars (two)
- 20-Fr van Buren urethral sound
- 18-Fr urethral catheter
- Small and medium-large Hem-o-lok clips (Teleflex Medical, Research Triangle Park, NC)
- 0 polyglactin suture (GS21) for dorsal venous complex
- 2-0 polydioxanone suture for posterior reconstruction
- 3-0 poliglecaprone (Monocryl) double-armed suture for anastomosis

Robotic-Assisted Laparoscopic Prostatectomy

- da Vinci S or Si HD Surgical System
- Endowrist Maryland bipolar forceps or PK dissector
- Endowrist curved monopolar scissors
- Endowrist ProGrasp forceps
- Endowrist large needle drivers (two)
- InSite Vision System with 0-degree and 30-degree lens
- 12-mm trocars (two)
- 8-mm metal robotic trocars (three if using a fourth robotic arm)
- 18-Fr urethral catheter
- Small and medium-large Hem-o-lok clips (Teleflex Medical)
- 0 polydioxanone suture for dorsal venous complex
- 2-0 polydioxanone suture for posterior reconstruction
- 3-0 Monocryl double-armed suture for anastomosis

Preoperative Preparation

Patient Preparation

The authors typically do not use a formal bowel preparation; however, a preoperative mechanical bowel preparation with magnesium citrate and a Fleet enema (C.B. Fleet Company, Inc., Lynchburg, VA) can be considered to help reduce colonic distention. A broad-spectrum antibiotic such as cefazolin is administered intravenously 30 minutes before skin incision. Continuing low-dose aspirin appears to be safe in patients undergoing RALRP; however, other blood thinners should be held for the appropriate durations (Leyh-Bannurah et al., 2014).

Informed Consent

In addition to bleeding, transfusion, and infection, patients undergoing LRP and RALRP must be aware of the potential for conversion to open surgery. As with open surgery, patients must be counseled on the risk for impotence, incontinence, incisional hernia, and adjacent organ injury (e.g., ureter, rectum, bladder, small bowel). The risks with general anesthesia must be presented to the patient because LRP and RALRP cannot be performed under regional anesthesia. In addition, it is appropriate for the surgeon to discuss his or her overall operative experience with radical prostatectomy, specifically in addition to the laparoscopic or robotic approach, and provide a realistic forecast of cancer control, as well as return to normal urinary and sexual function on the basis of each patient's unique characteristics. Use of validated questionnaires such as the Sexual Health Inventory for Men and the International Prostate Symptom Score allows for an objective assessment of baseline function and can help with forecasting postoperative recovery of sexual and urinary function.

Operating Room Personnel

LRP and RALRP require that the surgical team, including the scrub technician, circulating nurse, and surgical assistant(s), be fully trained and skilled in the instrumentation, operative setup, and technical steps of these minimally invasive procedures. Only one skilled assistant is generally required for these procedures, but a second assistant may be used if available to provide retraction of tissues. **For RALRP, it is important for the tableside assistant to have adequate training in not only basic laparoscopy but also specifically the mechanics, setup, and troubleshooting of the robotic system.** The scrub technician is also an integral part of the operative team and must be versed in the wide array of laparoscopic and robotic instruments that may be used to accomplish this procedure. Finally, using an anesthesiologist who is versed in the nuances and physiologic effects of prolonged pneumoperitoneum is vital in the success of this operation. Typical operating room equipment and setup for RALRP and LRP are shown in Fig. 156.1.

Patient Positioning

After induction of general endotracheal anesthesia, the patient is placed in the steep Trendelenburg position with the arms and hands carefully tucked and padded at the sides with “egg crate” padding to avoid injury to the median and ulnar nerves (Fig. 156.2A–C). Sequential compression stocking devices are placed on both legs and activated. The patient's legs are spread apart and supported by spreader bars to allow for access to the rectum and perineum. Alternatively, the patient's legs may be placed in stirrups in the low lithotomy position. The patient is then secured firmly to the table using heavy cloth tape and egg crate padding across the chest to help prevent the patient from sliding when in the steep Trendelenburg position (see Fig. 156.2D). This binding across the patient's chest may limit chest excursion and thereby decrease pulmonary compliance, making it important to check with anesthesia before moving on from this step in patient positioning. **Fixed shoulder rests should be avoided because this can result in compression injury to the shoulders and brachial plexus when in the steep Trendelenburg position.** Slight flexion of the table at the level of the hips may be required to properly dock the robotic arms; however, exaggerated flexion should be avoided so as to minimize the risk for femoral neurapraxia (see the Complications of Robotic Prostatectomy section later in this chapter). An orogastric tube and urethral catheter are placed to decompress the stomach and bladder, respectively. **Careful history-taking and padding of vulnerable body parts such as the hips, shoulders, knees, and calves are important to prevent pressure injury and neuromuscular complications** (see the Complications of Robotic Prostatectomy section).

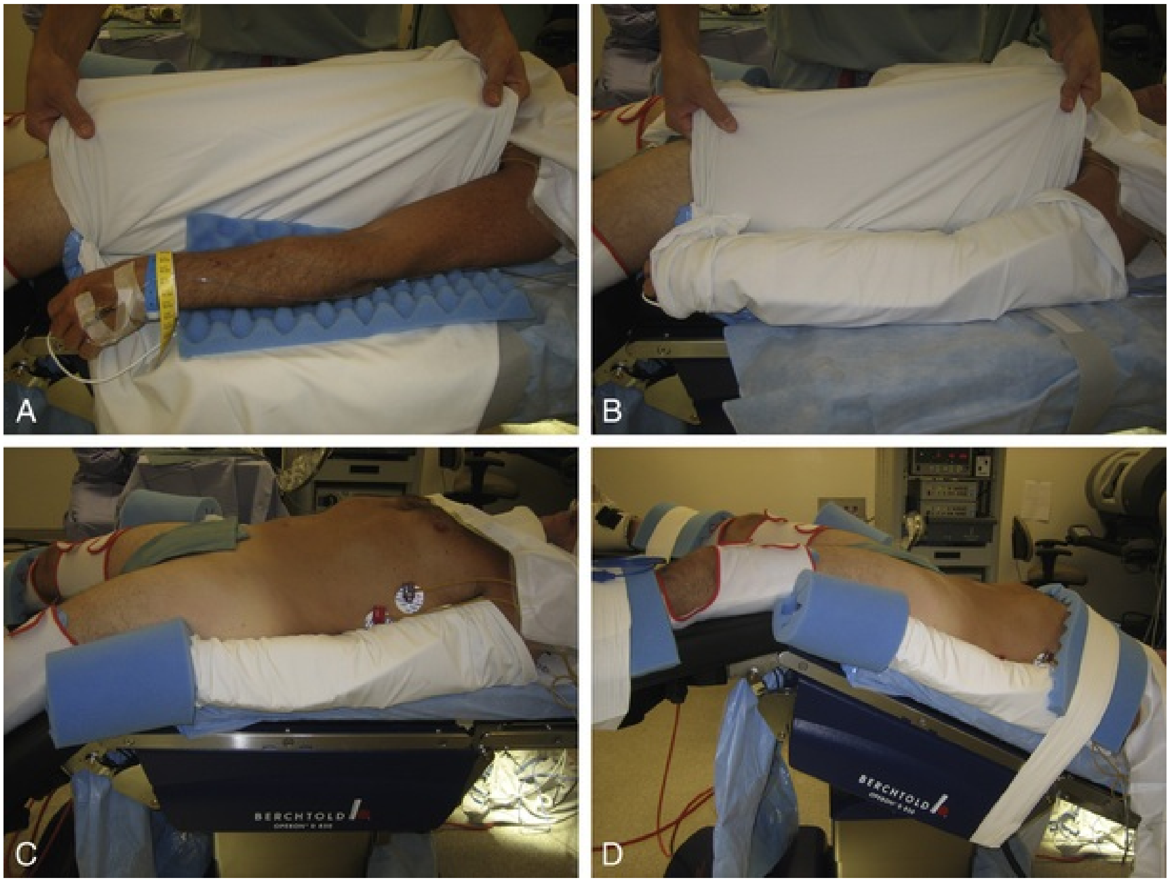

FIG. 156.2 Patient positioning for robotic-assisted radical prostatectomy. During positioning on the operating room table, the draw sheet and egg crate padding are used to help secure the patient's hands and arms to the side in the neutral position, taking great care to protect from injury to the median and ulnar nerves (A–C). To prevent the patient from sliding when in the steep Trendelenburg position, heavy cloth tape and egg crate padding are placed across the patient's chest (D).

Anesthesia Considerations

Both LRP and RALRP require general anesthesia. Because the patient's arms are tucked at the side and difficult to access, establishing accurate pulse oximetry, blood pressure cuff placement, and intravenous access is critical before final patient positioning. **The anesthesiologist must be aware of the potential consequences of carbon dioxide insufflation and pneumoperitoneum, including an initial vagal response, oliguria, and hypercarbia. Prompt adjustment in minute and tidal volumes may be required by the anesthesiologist in the event of rising end-tidal CO_2 levels and hypercarbia, which may lead to systemic acidosis if left uncorrected** (Meininger et al., 2004). **This is especially true in the early experience of a robotic surgeon and his or her team because operative times generally can be long.** Likewise, adjustments in CO_2 insufflation pressures may be required by the surgeon to reduce the risk for continued hypercarbia.

Intravenous fluid management can be difficult during RALRP, especially given that urine output is not reliably recorded secondary to the oliguria from the pneumoperitoneum and the bladder being opened for the majority of the procedure. The goal is to avoid too much urine being produced, thereby obscuring the operative field while maintaining appropriate intravascular volume and cardiac output (Giordano et al., 2017). A typical fluid resuscitation is 1.5 to 2 L of crystalloid solution, with the majority being given after the anastomosis is complete. Additional fluids should be consistent with blood loss and insensible fluid losses.

The steep Trendelenburg position can lead to facial, orbital, pulmonary, and laryngeal edema. Increased intraocular pressure can occur in patients in the exaggerated Trendelenburg position, but in patients undergoing RALRP this does not appear to have any apparent clinical long-term consequence, at least in healthy patients. However, there may be an increased risk for corneal edema and abrasion, making it even more important for the anesthesiologist to maintain good eye lubrication and protection. If significant facial or orbital edema is noted, laryngeal edema should be considered, and the anesthesia team should think about delaying extubation until the edema is reduced to avoid a potentially tenuous airway and the need for reintubation (Giordano et al., 2017). Taken together, given the potential for prolonged surgical times with a patient in the steep Trendelenburg position, especially in a surgeon's early experience, it is important to recognize these unique complications and maintain excellent communication between the surgeon and anesthesia team throughout the operation.

Key Points: Patient Selection, Instrumentation, and Preoperative Preparation for Laparoscopic and Robotic-Assisted Laparoscopic Radical Prostatectomy

- Regarding patient selection, it is strongly advised that patients with more complex anatomic challenges (e.g., large prostate size, large median lobe, morbid obesity, prior pelvic surgery, after radiation, after TURP) be avoided in a surgeon's early experience with LRP and RALRP; however, these patient features are not by themselves absolute contraindications for a minimally invasive approach to prostatectomy.

- Having a skilled bedside assistant who is well versed in basic laparoscopy, but also specifically in the mechanics, setup, and troubleshooting of the robotic system, can greatly facilitate RALRP procedures.
- Both the surgeon and anesthesiologist must be aware of the unique physiologic effects of prolonged pneumoperitoneum with patients in the steep Trendelenburg position, including hypercarbia and acidosis, corneal edema, increased intraocular pressure, and neurapraxia, and take the proper steps to prevent such complications.

Surgical Technique

Robotic-Assisted Versus Pure Laparoscopic Approach

Most of the principles and considerations for the surgical dissection are similar regardless of whether a pure laparoscopic or robotic-assisted approach is used. In general, the following discussion of technique and the pros and cons of various maneuvers and approaches apply to either surgical approach; however, the primary focus of this chapter will be on RALRP.

For RALRP, the da Vinci Surgical System is a master/slave system with three components: surgical robot (also called the patient side cart), surgeon console, and video cart. For the purpose of this chapter and for simplicity, the technique using the four-armed da Vinci Si HD system is described. The robot is docked at the foot of the operating table between the patient's legs. The da Vinci Xi system allows for side docking. The tableside assistant is responsible for docking/undocking the robot, suction-irrigation, retraction of tissues, passing sutures into the operative field, and robotic instrument changes. The surgeon is seated at the surgeon console, which provides a three-dimensional, 10× magnified, high-definition operative view and allows the surgeon to have complete control of all camera movements and three additional robotic arms. The surgeon's thumb and index or third fingers are inserted into master controls that allow natural hand and wrist movements to be precisely replicated by wristed instruments at the terminal ends of the robotic arms in real time.

Surgeons highly skilled in laparoscopy may find the robotic technology unnecessary and discover that they are equally as facile with pure laparoscopic suturing and dissection as with the robot (Guillonneau, 2005). **For most surgeons, however, the robotic technology significantly facilitates suturing of the vesicourethral anastomosis and aids in other aspects of the surgical dissection such as achieving the critical angles of dissection required to optimize cavernous nerve preservation.**

Transperitoneal Approach

The most common approach to LRP and RALRP is the transperitoneal anterior approach in which, after transperitoneal access and insufflation, the space of

Retzius is immediately entered and the prostate gland, seminal vesicle, and vasa are dissected from an anterior approach. This is in contrast with the transperitoneal retrovesical (or posterior) approach in which the seminal vesicles and vasa are initially approached and completely dissected behind the bladder near the cul-de-sac *before* the space of Retzius is entered. The transperitoneal access and approach is favored by most surgeons over the extraperitoneal approach because of the greater working space and familiar landmarks of the pelvis. For the purposes of this chapter, the transperitoneal anterior approach will be primarily described, with brief mention of the extraperitoneal approach.

Abdominal Access, Insufflation, and Trocar Placement

For a transperitoneal approach, pneumoperitoneum is established using either a Veress needle inserted at the base of the umbilicus or an open Hasson technique. Many patients have had prior abdominal or inguinal surgeries and the amount of adhesions can be difficult to predict. One must consider both the location of the incision and the procedure performed when deciding where to establish pneumoperitoneum. The left upper quadrant is often a safe location in patients with prior midline scars. After initial insufflation, we prefer to use a visual obturator to enter the peritoneal cavity. An offset working laparoscope can be used through a single trocar to release adhesions to create enough space for additional trocar placement in patients who have had prior surgery and present with significant adhesions. Once additional trocars are placed, the robot can be used to release any additional adhesions in the lower abdomen and pelvis. After initial trocar placement, CO_2 insufflation pressure in general is maintained between 12 and 15 mm Hg. Secondary trocars are then placed under laparoscopic view. For RALRP, an example of a trocar configuration is shown in Fig. 156.3A. A 12-mm trocar is initially placed slightly inferior to or above the umbilicus for insertion of the stereo-endoscope at a distance of 15 to 17 cm from the pubic symphysis. Three 8-mm metal robotic trocars are used by the working robotic arms of the surgeon while the assistant provides retraction, suction, and irrigation and passes clips and sutures via the 12- and 5-mm trocars placed along the patient's right side. The surgeon controls camera movement by depressing a foot pedal and using brief, simultaneous arm movements to control camera positioning and rotation. Endoscopes with either angled (30-degree) or straight-ahead (0-degree) viewing are available and interchangeable at various portions of the procedure. In general, most surgeons use the 0-degree endoscope lens throughout the operation; however, some surgeons prefer to switch to the 30-

degree down lens when approaching the bladder neck, NVBs, and apical dissection, especially in complex cases such as morbidly obese patients, large prostates, prior TURPs, and patients with a narrow pelvis (Ganapathi et al., 2017). Fig. 156.3B depicts the trocar configuration for LRP. The surgeon stands at the patient's left side and operates through the two pararectus trocars, while one or two assistants use the lateral-most trocars. The endoscope may be held and controlled by the surgical assistant or alternatively stabilized by an automated endoscopic system for optimal positioning of the AESOP robotic arm.

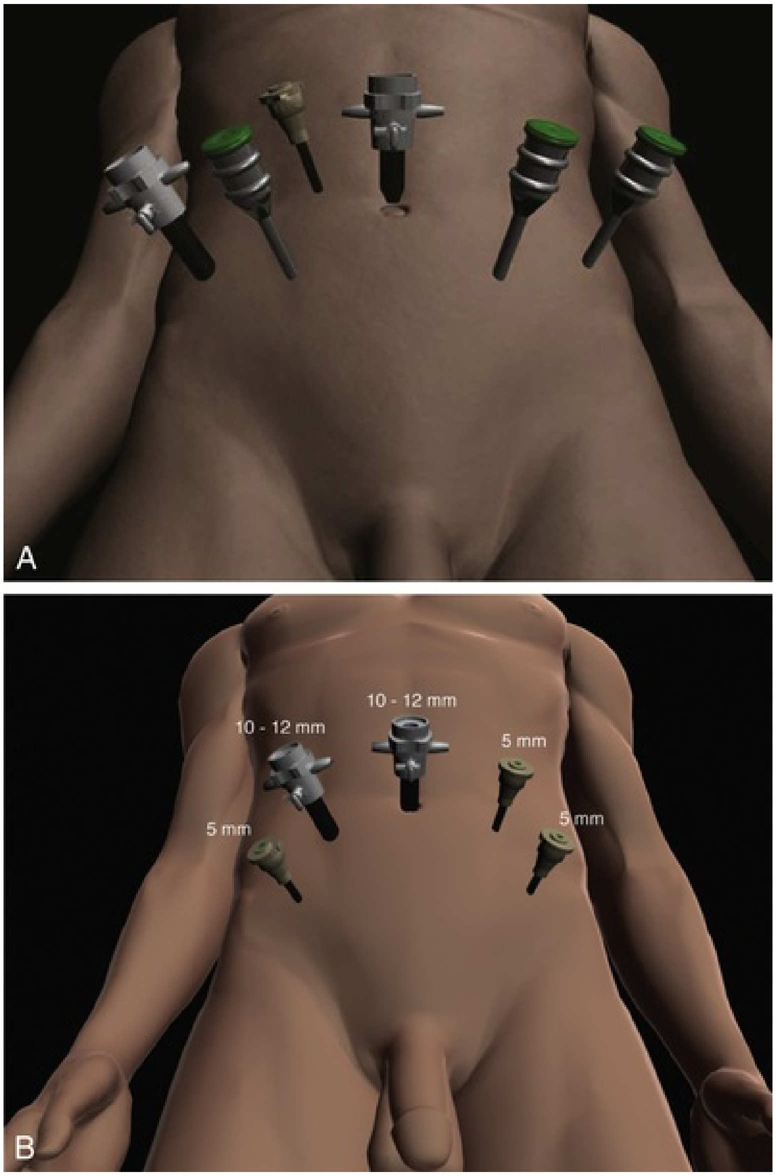

FIG. 156.3 Trocar configuration for robotic-assisted laparoscopic prostatectomy (A) and laparoscopic radical prostatectomy (B).

Extraperitoneal Approach

For an extraperitoneal approach, a 1.5-cm incision is made at the level just beneath the umbilicus, and dissection is carried out down through the anterior rectus sheath. Using blunt finger dissection, a space is created immediately anterior to the posterior rectus sheath and underlying peritoneum. A trocar-mounted balloon dilator device (PDB Balloon, Covidien Autosuture, Mansfield, MA) is inserted into the preperitoneal space anterior to the posterior rectus sheath and advanced down to the pubis along the midline. Using a 0-degree, 10-mm endoscope inserted through the balloon trocar, approximately 500 mL of air is inflated to develop the space of Retzius under direct laparoscopic view (Fig. 156.4). Secondary trocars are then inserted as described earlier in the discussion of the laparoscopic view. The operation then proceeds in the exact manner as in the transperitoneal anterior approach.

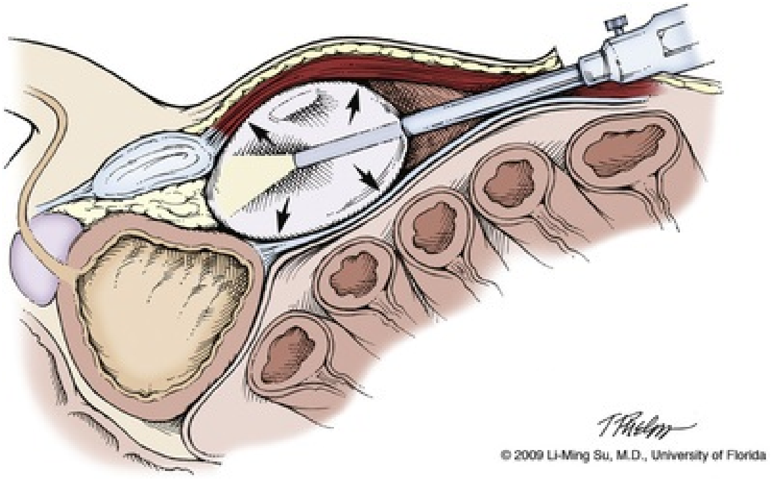

FIG. 156.4 Creation of working space for extraperitoneal pure laparoscopic or robotic-assisted radical prostatectomy using a trocar-mounted balloon dilator device. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

Pros and Cons of Extraperitoneal Versus Transperitoneal Approach

In a retrospective comparison between extraperitoneal and transperitoneal LRP, Hoznek et al. (2003) found that the mean operative time was shorter with the extraperitoneal approach (169.6 vs. 224.2 minutes, $P < .001$), with the greatest time saved during access to the space of Retzius. They suggested that time to full diet was less with the extraperitoneal approach versus the transperitoneal LRP approach (1.6 vs. 2.6 days, $P = .002$) because the peritoneum had not been violated and postoperative ileus was minimized. Eden et al. found a statistically significant advantage in operative time, hospital stay, and return of early continence favoring patients undergoing extraperitoneal versus transperitoneal LRP, postulating that earlier return to urinary control may be secondary to less bladder dissection and, perhaps, less bladder dysfunction compared with transperitoneal LRP (Eden et al., 2004). **Most studies, however, found little or no difference in operative time and perioperative outcomes between transperitoneal and extraperitoneal approaches** (Atug et al., 2006; Brown et al., 2005a; Cathelineau et al., 2004; Erdogru et al., 2004).

With an extraperitoneal approach, the simultaneous laparoscopic management of concurrent inguinal hernias using prosthetic mesh is feasible (Stolzenburg et al., 2003). Simultaneous inguinal herniorrhaphy has also been reported during transperitoneal LRP; however, proper coverage of the mesh prosthesis is necessary using peritoneal flaps, omentum, or a second absorbable mesh to reduce the risk for direct contact between the mesh and bowel with subsequent fistula (Allaf et al., 2003). The extraperitoneal technique may be preferable in patients with previous extensive abdominal surgery or morbid obesity. **With the extraperitoneal approach, the peritoneum acts as a natural barrier, minimizing the potential for bowel injury and preventing the bowels from falling into the operative field and obscuring the surgeon's view. Additionally, the patient may not need to be in the steep Trendelenburg position, which could be beneficial in obese patients or patients with pulmonary compromise. One limitation with the extraperitoneal approach is the reduced working space compared with the relatively larger working space of the peritoneal cavity gained with transperitoneal access.** This is especially relevant when a well-meaning assistant attempts to clear the operative field of blood or smoke. Suctioning can evacuate CO_2 and rapidly collapse the already limited extraperitoneal working space, thus significantly compromising visualization; however, this may be less of a problem with high-flow insufflators. A second limitation to the extraperitoneal approach is in patients with a history of laparoscopic extraperitoneal mesh herniorrhaphy because the retropubic space is often obliterated, making attempts at extraperitoneal access challenging. Finally, higher CO_2 absorption has been reported with extraperitoneal versus transperitoneal insufflation, requiring a higher minute volume to compensate for hypercarbia and associated acidosis (Meininger et al., 2004). **Overall, whether to use an extraperitoneal or transperitoneal approach for LRP or RALRP is largely a matter of surgeon preference and experience, and there is no consistently demonstrated advantage for either approach. Surgeons should consider becoming proficient in both techniques to best individualize patient care.**

Developing the Space of Retzius

After abdominal access and trocar placement for the transperitoneal anterior approach, the pelvic contents are inspected (Fig. 156.5) and adhesions are lysed if present. Frequently, adhesions are noted between the sigmoid colon and the left lateral pelvic side wall. These adhesions should be sharply released to allow the sigmoid colon to be retracted out of the pelvic cavity, providing optimal visualization of the bladder and prostate during subsequent steps of the operation. The initial step is entry and development of the space of Retzius. The bladder is dissected from the anterior abdominal wall by dividing the urachus high above the bladder and incising the peritoneum bilaterally immediately lateral to the medial umbilical ligaments using monopolar scissors. Care should be taken to thoroughly cauterize the obliterated umbilical vessels to avoid unwanted bleeding. The presence of prevesical fatty alveolar tissue confirms the proper plane of dissection within the space of Retzius. Applying posterior and cephalad traction on the urachus, the retropubic space is rapidly developed with a combination of blunt and sharp dissection along the relatively avascular plane (Fig. 156.6). Dissection should be maintained within the pelvic brim to avoid inadvertent injury to the epigastric vessels anteriorly and the iliac vessels laterally. **Lateral dissection of the bladder is carried out down toward the crossing of the medial umbilical ligaments and vas deferens to ensure optimal mobility of the bladder, which minimizes tension when accomplishing the vesicourethral anastomosis later in the operation.** All adipose tissue overlying the prostate is removed using sharp dissection and electrocautery as needed, and the superficial branches of the DVC are coagulated using bipolar electrocautery.

FIG. 156.6 Division of urachus and entry into the space of Retzius. Cephalad traction on the urachus with the left hand helps identify the fatty alveolar tissue immediately anterior to the bladder, which marks the proper plane of dissection. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

At this point, visible landmarks include the anterior aspect of the bladder and prostate, puboprostatic ligaments, endopelvic fascia, and pubis (Fig. 156.7). The endopelvic fascia and puboprostatic ligaments are sharply divided, exposing levator muscle fibers attached to the lateral and apical portions of the prostate.

These fibers are meticulously preserved and bluntly dissected from the surface of the prostate exposing the deep DVC and urethra at their confluence with the prostatic apex. Electrocautery is avoided if possible to minimize thermal damage to the pelvic musculature, external sphincter, and nearby NVBs.

FIG. 156.7 Retropubic view of the bladder and prostate after entry into the space of Retzius. The fatty tissue overlying the anterior aspect of the prostate has been removed, exposing the puboprostatic ligaments, superficial and deep dorsal venous complex, and endopelvic fascia. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

Accessory pudendal arteries traveling longitudinally along the anteromedial aspect of the prostate are easily recognized during LRP and RALRP. Attempt at preservation of these arteries is important for erectile function because in some men these arteries may be the dominant source of arterial blood supply to the corpora cavernosa (Nehra et al., 2008). These accessory arteries can usually be preserved, although separation of the artery from the prostatic apex and deep DVC can sometimes be challenging.

Ligation of the Deep Dorsal Venous Complex

As with open surgery, different methods have been described for control of the deep DVC. **A common observation, though, is that the profuse bleeding, which is sometimes encountered during open surgery, is less apparent because of the tamponade effect on venous bleeding offered by the pneumoperitoneum, even when the DVC is inadvertently entered.** During RALRP, the ProGrasp forceps can be used for fixed cephalad retraction of the prostate and bladder to achieve optimal exposure of the DVC and prostatic apex before DVC ligation. Similar retraction can be applied by the surgical assistant during LRP. The deep DVC is suture ligated using a 0-polydioxanone suture or polyglactin suture as close to the pubis and as far from the prostatic apex as possible (Fig. 156.8). **Securing the deep DVC as far distal from the prostatic apex as possible can help minimize iatrogenic entry into the prostatic apex during later division of the DVC.** For this reason, it is the authors’ opinion that the puboprostatic ligaments should be completely divided before ligation of the DVC to allow for adequate exposure and access to the most distal portion of the DVC as it traverses beneath the pubic symphysis. The needle is passed beneath the DVC and anterior to the urethra. A second more distal DVC stitch can be placed and used to suspend the DVC to the inferior pubic symphysis.

the apex. *Inset* demonstrates the proper passage of the needle immediately anterior to the urethra. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

An alternative method to DVC ligation is the use of a laparoscopic linear stapling device, which ligates and divides the DVC in one step (Ahlering et al., 2004; Nguyen et al., 2008). Lastly, management of the DVC can also be left until the final steps of prostatic apical dissection and division of the urethra. At this point, the DVC can be sharply divided and then oversewn in a vertical mattress fashion. It may be helpful to briefly increase the pneumoperitoneum to 20 mm Hg during this step to tamponade venous bleeding and improve visualization. A back-bleeding suture may be placed along the anterior base of the prostate to help identify the contour of the prostate and aid in subsequent bladder neck identification and transection.

Bladder Neck Identification and Transection

Proper identification of the bladder neck during RALRP and LRP can be initially challenging because of the lack of tactile feedback in delineating the precise margin between the prostate and bladder. **Several maneuvers are helpful in identifying the proper plane of dissection and in minimizing inadvertent entry into the base of the prostate. First, visual identification of the point of transition of the prevesical fat to the anterior prostate now devoid of fat can serve as a guide. Second, intermittent and repetitive caudal retraction of an inflated urethral catheter balloon can help identify and confirm the approximate transition between bladder neck and prostate. Note that any deviation of the balloon away from the midline signifies the likely presence of a median lobe of the prostate. Note that this maneuver may be less reliable in patients with a TURP, where the balloon may fall into the TURP defect, misleading the surgeon in transecting the bladder neck in a too-distal location. In such cases, a more proximal division of the bladder neck is advised. Third, using a forceps to grasp and retract the dome of the bladder in a cephalad direction results in tenting of the bladder neck at its attachment to the prostate. Finally, further confirmation of this margin between the bladder and prostate is made by a bimanual “palpation” or pinch of the bladder neck using the tips of two robotic or laparoscopic instruments.**

The anterior bladder is divided horizontally using monopolar scissors along the midline until the urethral catheter is identified. **The anterior bladder neck incision should not be carried too far laterally because branches of the bladder pedicle are often encountered, resulting in unwanted bleeding.** The balloon is decompressed, and the tip of the urethral catheter is brought through the bladder neck opening and lifted anteriorly with the assistant applying countertraction externally at the penile meatus to “suspend” the prostate.

The posterior bladder neck is inspected for the presence of a median lobe and to locate the ureteric orifices. If a vertical drop-off of the posterior bladder neck mucosa is noted, this often suggests the absence of a median lobe. Alternatively, if a mass effect from a large median lobe is identified, it may be delivered out of the bladder by anterior retraction with a ProGrasp forceps. However, further exposure by a transverse or even sagittal cystotomy may be required to visualize beneath a large, protruding median lobe and identify the posterior bladder neck. **The posterior bladder neck is horizontally divided with monopolar scissors, staying again along the midline to avoid bleeding from the lateral pedicles** (Fig. 156.9). **Dissection is carried out in a 45-degree downward angle to avoid entry into the base of the prostate or inadvertent entry into the posterior wall of the bladder.** In case of a prior TURP, the bladder neck margin is less evident and often distorted as a result of prior resection and scarring. Careful inspection is made of the posterior bladder neck, paying specific attention to the location of the ureteric orifices because they are often found very close to the posterior bladder neck margin. Attempt at bladder neck sparing should be avoided in post-TURP and median lobe cases. Switching to a 30-degree down lens may improve visualization in these cases. When in doubt, the posterior bladder neck should be divided slightly more proximally in these particular cases so as to avoid inadvertent entry into the prostate gland with a resultant positive bladder neck margin.

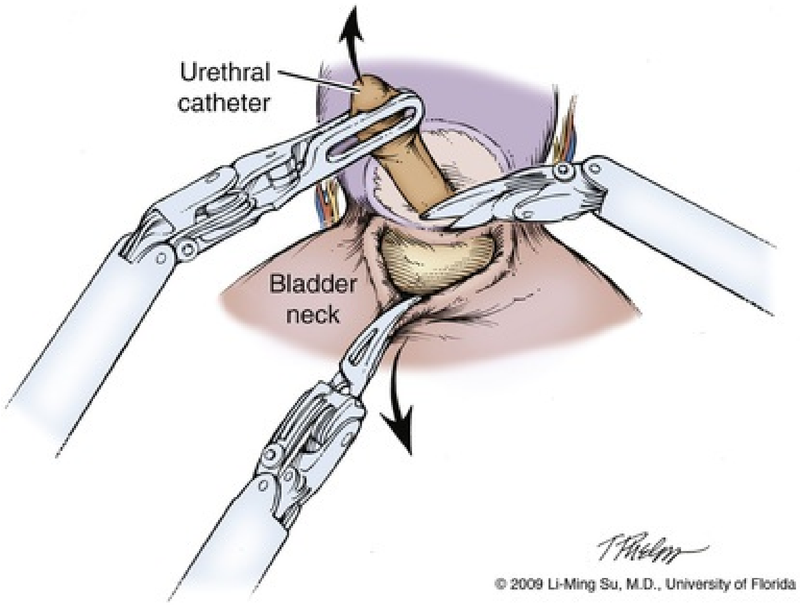

FIG. 156.9 Division of the posterior bladder neck. An assistant or ProGrasp forceps is used to grasp and elevate the urethral catheter anteriorly, providing exposure to the posterior bladder neck. Dissection is carried out along the midline, avoiding bleeding from the lateral pedicles. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

Dissection of the Seminal Vesicles and Vasa Deferentia

After bladder neck transection, the seminal vesicles and vasa deferentia are individually identified, dissected, and divided, minimizing electrocautery if possible to prevent damage to the nearby NVBs (Fig. 156.10). One unique distinction between the transperitoneal anterior and retrovesical approaches is in dissection of the seminal vesicles and vasa deferentia. During the transperitoneal retrovesical approach, the initial step of the operation is dissection of the vasa deferentia and seminal vesicles deep within the cul-de-sac. After abdominal access, the vasa are dissected from lateral to medial toward their confluence at the ejaculatory ducts. The seminal vesicles are found immediately lateral and slightly posterior to the distal portion of the vasa and are dissected free from the nearby NVB using hemoclips while avoiding the use of thermal energy (Fig. 156.11). With the dissection of the seminal vesicles and vasa now completed under excellent vision, these structures are simply grasped and brought through the opening once the bladder neck is divided from the prostate base later in the operation. **This retrovesical approach to the seminal vesicles and vasa**

deferentia is particularly useful in cases of a median lobe in which identification and dissection of these structures by the anterior approach may be more challenging because of the physical presence of the protruding median lobe, which may obscure the identification of the vasa and seminal vesicles, in addition to the presence of urine and blood in the operative field.

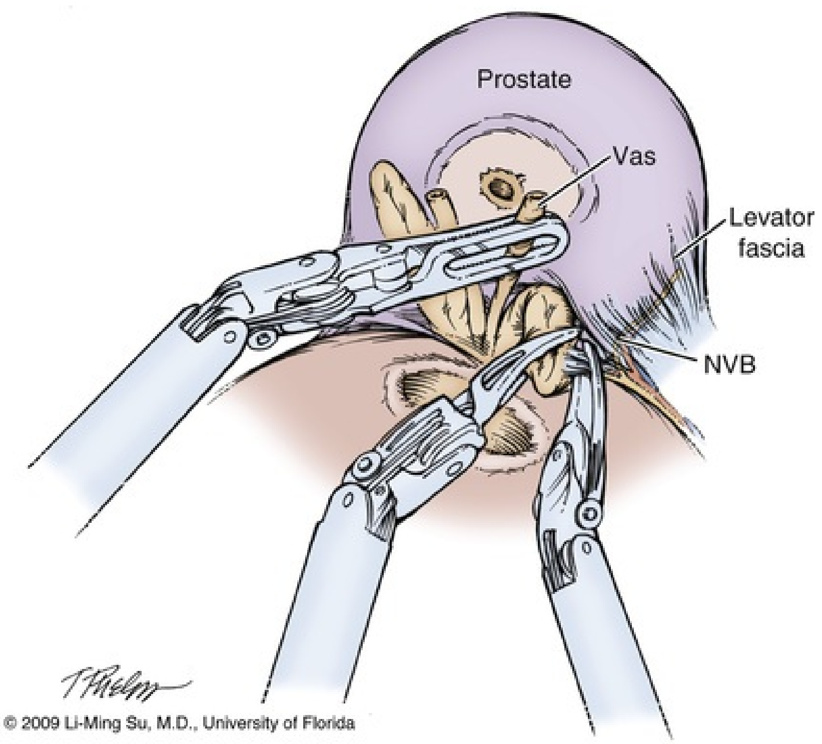

FIG. 156.10 Dissection of seminal vesicles and vasa deferentia via the transperitoneal anterior approach. The seminal vesicles and vasa are identified and dissected within the opening created between the posterior bladder neck and prostate following division of the bladder neck. Hemoclips are used in lieu of electrocautery to avoid thermal injury to the nearby neurovascular bundles (NVBs). (Copyright Li-Ming Su, MD, University of Florida, 2009.)

Development of the Plane Between the Prostate and Rectum

Separation of the posterior prostate from the anterior rectal wall is a key surgical maneuver to avoid rectal injury but also permit adequate identification of the medial aspect of the prostatic pedicles and establish the medial border of the NVBs. Development of this plane in an antegrade fashion is a maneuver that is less familiar to surgeons who are experienced with open surgery but one that is rapidly adaptable to laparoscopic and robotic approaches. Anterior retraction of the vasa deferentia and seminal vesicles by a surgical assistant or the robotic ProGrasp forceps helps with identification of the proper plane for the initial dissection (Fig. 156.12). The authors typically make a 2- to 3-cm horizontal incision through the posterior layer of Denonvilliers fascia approximately 0.5 cm below the base of the seminal vesicles.

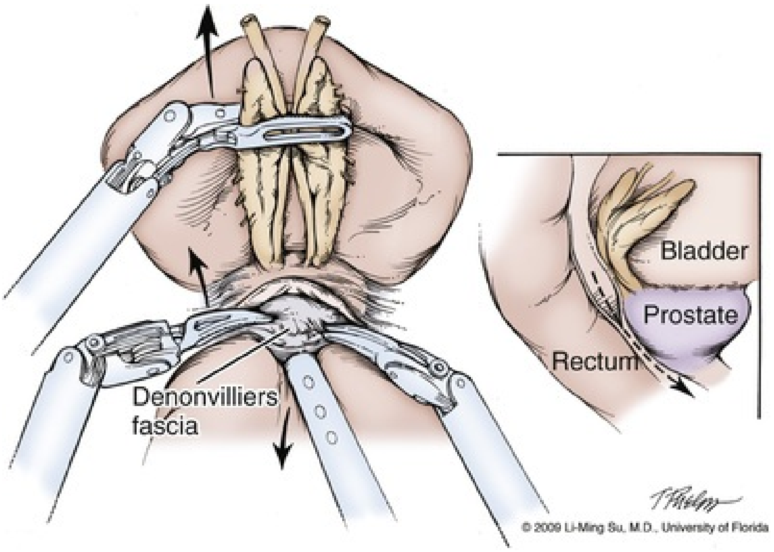

FIG. 156.12 Development of the plane between the prostate and rectum. As the assistant or ProGrasp forceps is used to apply anterior traction on the seminal vesicles and vasa deferentia and downward traction on the rectum, a transverse incision is made in Denonvilliers fascia below the seminal vesicles, and blunt dissection is used to develop a plane between the posterior prostate and the rectum. *Inset* demonstrates the direction of dissection toward the prostatic apex without electrocautery. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

Denonvilliers fascia is an inferior extension of the peritoneal cul-de-sac that lies between the prostate and rectum. In patients with low-risk and low-volume disease for whom extensive NVB dissection is planned, Denonvilliers fascia can be separated from the posterior prostate by careful blunt and sharp dissection, dissecting between this layer and the prostatic fascia. This plane of dissection is relatively avascular and should be carried all the way to the prostatic apex and laterally to the medial aspect of the prostatic pedicle. Switching to a 30-degree up lens may facilitate further apical dissection. **Alternatively, when a wider margin of tissue is desired along the posterior aspect of the prostate, such as in cases of palpable disease, Denonvilliers fascia should be sharply incised.**

This allows immediate entry into the anterior perirectal fat plane of dissection. Good visualization can be achieved as the dissection proceeds distally toward the apex staying between Denonvilliers fascia anteriorly and the anterior propria fascia of the rectum posteriorly.

Substantial bleeding typically suggests that the dissection may be too close to the prostate. If difficulty is encountered in establishing the proper plane of dissection, a new attempt can be directed to one side or the other of the initial entry point. Once the proper plane is entered, the dissection characteristically progresses rather smoothly by blunt dissection. The rectal wall should be mobilized far enough laterally and distally so as to minimize any further risk for rectal entry on subsequent steps of the operation.

Prostatic Pedicle Control

Various methods have been described for control of the prostatic pedicle. Some techniques use pure electrocautery, either monopolar or bipolar. **Because of the propagation of thermal energy through tissue, which may result in damage to the nearby NVB, limitation of the use of electrocautery is advised and, if possible, should be avoided during division of the prostatic pedicle.** Locking polymer Hem-o-lok clips (Teleflex Medical, Research Triangle Park, NC) are commonly employed for ligation of the prostatic pedicles with sharp athermal transection. However, engagement of the clipping mechanism with these hemoclips does require good proximal and distal delineation and thinning of the pedicle tissue for the clipping mechanism to engage. It is important to remove any clips that fall off and to avoid placing these clips in close proximity to the vesicourethral anastomosis as migration of the clips into the bladder can lead to postoperative voiding symptoms, hematuria, recurrent urinary tract infections, and bladder stones (Fig. 156.13). This is best facilitated by adequate mobilization of the rectum and lateral prostate for identification of the prostatic pedicle. Application of a temporary bulldog clamp to the pedicle with subsequent suturing of the pedicle after the prostate specimen has been removed also has been described (Ahlering et al., 2005; Gill et al., 2005). Regardless of the method used, though, successful division of the prostatic pedicle in the correct anatomic location is an important step in avoiding positive margins and damage to the nearby NVB.

Preservation of the Neurovascular Bundle

Preservation of the periprostatic parasympathetic nerve fibers important for erectile function is one of the key and most technically demanding maneuvers during radical prostatectomy, regardless of surgical approach. **Increasingly, it is recognized that the periprostatic nerves of significance have a more diffuse and highly variable course than previously thought**, **but there is a confluence of nerves along the posterolateral aspect of the prostate commonly believed to be the predominant nerves responsible for penile erections** (Costello et al., 2004; Lunacek et al., 2005; Takenaka et al., 2004). Nerve tissue extends posteriorly around the prostate, forming a virtual hammock of nerves. In addition, nerve fibers can be identified in the periprostatic tissue along the more anteromedial portion of the prostate gland, although there is still debate about their relative function and contribution to penile erections. A well-performed, nerve-sparing radical prostatectomy takes all of these considerations into account and preserves as much periprostatic nerve tissue as possible, both from a qualitative and quantitative standpoint.

The superb visualization of the periprostatic tissues with minimally invasive surgery has led to a greater appreciation of the periprostatic fascial layers. Although there is some confusion in the literature regarding the terminology used for the various fascial layers, an *extrafascial* dissection typically implies dissection laterally between the lateral prostatic fascia and the levator fascia and posteriorly between Denonvilliers fascia and the anterior propria rectal fascia. **An *interfascial* dissection is carried out laterally between the prostatic fascia and the levator fascia and posteriorly between Denonvilliers fascia and the posterior surface of the prostate** (Fig. 156.14). **This is the preferred approach in patients with presumed organ-confined disease because it permits safe preservation of the cavernous nerves without violating the anatomic limits of the prostate gland and capsule.** Historically the periprostatic vasculature within the interfascial space has been used as a macroscopic landmark and visual surrogate for identifying and preserving the cavernous nerves. Patel et al. suggested that a dominant periprostatic artery specifically can be identified in 73% of cases during RALRP and can serve as a consistent landmark for cavernous nerve preservation (Patel et al., 2012). Finally, an *intrafascial* dissection is carried out between the prostatic capsule and the prostatic fascia and leaves virtually no periprostatic tissue overlying the prostate. Although technically feasible, this approach risks a higher incidence of positive margins because of the relatively closer dissection to the prostate gland.

FIG. 156.14 Cross-section of the prostate demonstrating the periprostatic fascial planes with respect to the location of the neurovascular bundles (NVBs). The dashed line indicates the direction of interfascial dissection (i.e., between the levator and prostatic fascia) to accomplish a high anterior release of the NVB from the prostate and establish the lateral NVB groove. The solid line indicates the incision made for a standard release of the NVB. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

Damage to the NVB can occur because of direct incision, entrapment in a suture or clip, thermal injury, or traction. Some surgeons advocate release of the NVB from the prostate before mobilization of the specimen to help avoid traction injury. **With the antegrade approach to NVB dissection typically used for LRP and RALRP, identification and at least partial release of the NVB along the lateral aspect of the prostate before controlling the prostatic pedicle can help drop the neurovascular tissue away from the gland and permit a more precise placement of hemoclips on the pedicle while preventing inadvertent entrapment of the nerve bundles.** To accomplish this, the levator fascia is first incised sharply along the anteromedial aspect of the midportion of the prostate entering into the interfascial plane of dissection (Fig. 156.15). Blunt dissection is carried out along the shiny, white-appearing prostatic fascial plane, gently sweeping the NVB off of the prostate in a posterolateral direction, thus partially releasing the NVB and developing a visible NVB groove. This groove serves as a visible landmark for precise hemoclip placement and division of the prostatic pedicle while avoiding entrapment of the NVB (Fig. 156.16). The ergonomics and scaled motion of the wristed robotic instruments are helpful in achieving this delicate dissection. During LRP, specially designed fine-tipped (0.8-mm) dissectors have been described to aid in NVB dissection and preservation (Su et al., 2004). Some discussion and debate has centered on how far anteriorly on the prostate the interfascial dissection of the nerve bundles should be performed. It is uncertain whether high release (vs. standard release) of the NVBs preserves important nerves or simply allows for a physical handle to permit more precise, meticulous dissection and preservation of the true cavernous nerves located at the 5-o'clock and 7-o'clock positions without direct manipulation of these main nerve fibers (see Fig. 156.14). **However, there is a general consensus that thermal energy should be minimized and, ideally, completely avoided during dissection of the NVB as these microscopic parasympathetic nerve fibers are highly susceptible to thermal injury, as demonstrated in both animal and human studies** (Ahlering et al., 2005; Ong et al., 2004). After completion of the NVB dissection, bleeding along the NVBs is generally minimal and may require no specific hemostatic measures. However, small arteries or a larger venous sinus may require suturing to achieve hemostasis with site-specific small tissue bites used to avoid entrapment of adjacent nerves.

FIG. 156.16 Developing the interfascial plane of dissection. Using blunt dissection, the nerve bundle is partially released from the prostate in a posterolateral direction, forming a visible lateral neurovascular bundle *(NVB)* groove. This step serves to delineate the prostatic pedicle and course of the nerve bundle and allow for precise placement of hemoclips, while avoiding nerve entrapment. (Copyright Li-Ming Su, MD, University of

Florida, 2009.)

Patients with extremely large prostate glands (especially those >100 g) offer a unique challenge during preservation of the NVB. Maneuvering a large prostate gland in the tight confines of the pelvic cavity can be challenging, especially during exposure of the prostatic pedicles and NVB. Effective exposure of tissues by the surgical assistant, as well as the fourth robotic arm, and potentially switching to a 30-degree down lens may be useful in such cases.

Apical Dissection

The prostatic apex is a common location for tumor involvement and the most common site of positive margins with radical prostatectomy. Further, the steps required for apical dissection are crucial to preservation of erectile function and avoidance of urinary incontinence. The visualization of the operative field and the ability to limit bleeding from the deep DVC facilitate apical prostatic dissection during LRP and RALRP.

Up to this point in the operation, antegrade dissection of the prostate has permitted complete mobilization of the lateral, base, and posterior prostate, leaving division of the deep DVC and urethra from the prostatic apex for last. **It is critical to avoid entry into the anterior prostate during division of the deep DVC because this may result in an iatrogenic positive margin.** If the previously placed DVC suture appears to be too proximal in its location, risking iatrogenic entry into the prostatic apex during transection, the surgeon should feel comfortable removing this stitch to achieve a wide enough margin of transection at the apex and simply resuturing the DVC once it is divided. Bleeding from the deep DVC can be kept to a minimum by transiently increasing the CO_2 insufflation pressure to 20 mm Hg to improve the tamponade effect on venous bleeding.

Once the DVC is divided, there should be good visualization of the prostatic apex and its junction with the urethra (Fig. 156.17). **The anatomy of the prostatic apex is highly variable and should be carefully inspected before division of the urethra. As much urethral length as possible should be maintained, but a protruding anterior or posterior lip of prostate must be recognized, so as to avoid inadvertently leaving prostatic tissue behind.** Leaving a small rim of urethra along the prostatic apex may be advisable to reduce the incidence of apical positive margins because this does not appear to have an adverse effect on the return of urinary continence (Borin et al., 2007). Sharp dissection with limited use of electrocautery is preferred during the prostatic apical dissection and division of the urethra, to prevent thermal injury to the nearby external striated sphincter and NVBs.

FIG. 156.17 Division of urethra. After division of the deep dorsal venous complex, the anterior and posterior urethra is divided sharply without electrocautery. A small rim of urethra may be safely left on the prostatic apex to avoid an iatrogenic positive apical margin. Great care must be taken to avoid damage to the nearby nerve bundles. *NVB,* neurovascular bundle. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

Intraoperative Inspection of Prostate

On completely freeing the prostate gland and before entrapment of the

specimen, the entire surface of the gland can be inspected to assess the adequacy of resection and integrity of the tissues covering the prostate specimen. If concern exists regarding a close surgical margin, additional tissue may be excised specific to the location of concern; however, with experience this should rarely be necessary.

Pelvic Lymphadenectomy

It is generally at this time that pelvic lymphadenectomy takes place, because prior mobilization of the bladder allows for excellent exposure of the obturator lymph node region and iliac vessels. The extent of pelvic lymphadenectomy remains controversial but can be tailored on the basis of cancer risk categorization, including PSA, clinical stage, and Gleason score. Technical description of a standard versus extended laparoscopic pelvic lymphadenectomy follows later in this chapter. It is advised that hemoclips be used during pelvic lymphadenectomy to minimize the risk for developing a postoperative lymphocele.

Entrapment of Specimens

The prostate and pelvic lymph nodes are entrapped within a 10-mm laparoscopic entrapment sack introduced into the abdomen by the surgical assistant through the 12-mm assistant trocar and stored in the abdomen until completion of the operation.

Bladder Neck Reconstruction

The bladder opening is often slightly larger than the urethral lumen, but a parachuting effect can be achieved during the vesicourethral anastomosis that allows direct approximation of the bladder neck to the urethra. **In the event of a large prostate gland, median lobe, or prior TURP, the bladder neck often may be disproportionately larger than the urethra and thus may require extensive reconstruction before performing the anastomosis. In such cases, a tennis racquet handle closure can be performed using absorbable suture either posteriorly or anteriorly to reduce the size discrepancy between the bladder neck and urethra. Often, in these circumstances, the ureteric orifices are located at or near the posterior margin of the bladder neck,**

where they are at risk for injury or obstruction during suturing of the anastomosis. It is imperative to identify their precise location in these unique circumstances before proceeding with bladder neck reconstruction. If they cannot be adequately visualized, intravenous methylene blue or indigo carmine can be given. In such cases, the ureteric orifices can be imbricated by placing a few interrupted sutures at the 5-o'clock and 7-o'clock positions along the posterior bladder neck using 3-0 polyglactin or polydioxanone suture. This maneuver can help avoid inadvertent sutures passing through or near the ureteric orifices during the anastomosis and at the same time reduce the size of the bladder neck opening. Alternatively, ureteral stents may be placed to protect the integrity of the ureteric orifices during completion of the anastomosis and then removed immediately or postoperatively in a delayed fashion once the anastomosis has healed.

Posterior Support of the Vesicourethral Anastomosis

As a result of prostatectomy, the posterior supportive layers of the bladder and prostate are divided, including Denonvilliers fascia and its confluence with the posterior rhabdosphincter. Reports of attempts at reconstruction of these posterior supportive structures have suggested improvement in earlier postoperative return of urinary continence (Rocco et al., 2007). Although the exact mechanism remains unclear, suggested mechanisms include reestablishment of the posterior anatomic support to the bladder and urethra, improving urethral coaptation during voiding, reduced tension at the vesicourethral anastomosis, and increase in the functional length of the striated urethral sphincteric complex. Others have found no significant benefits to reconstructing the support of the vesicourethral anastomosis (Menon et al., 2008). **Despite this ongoing debate, many believe that, at the very least, this step reduces the distance between the bladder neck and urethra, thus facilitating completion of a tension-free vesicourethral anastomosis.** Reconstituting the posterior support to the anastomosis is accomplished by reapproximating the remnant Denonvilliers fascia and posterior bladder neck to the posterior rhabdosphincter beneath the urethra using a running continuous 2-0 poliglecaprone (Monocryl) suture before completion of the vesicourethral anastomosis (Fig. 156.18). Resuspension of the anastomosis and distal bladder neck to the arcus tendineus is used by some to restore anterior urethral support and preserve the vesicourethral angle (Tewari et al., 2007).

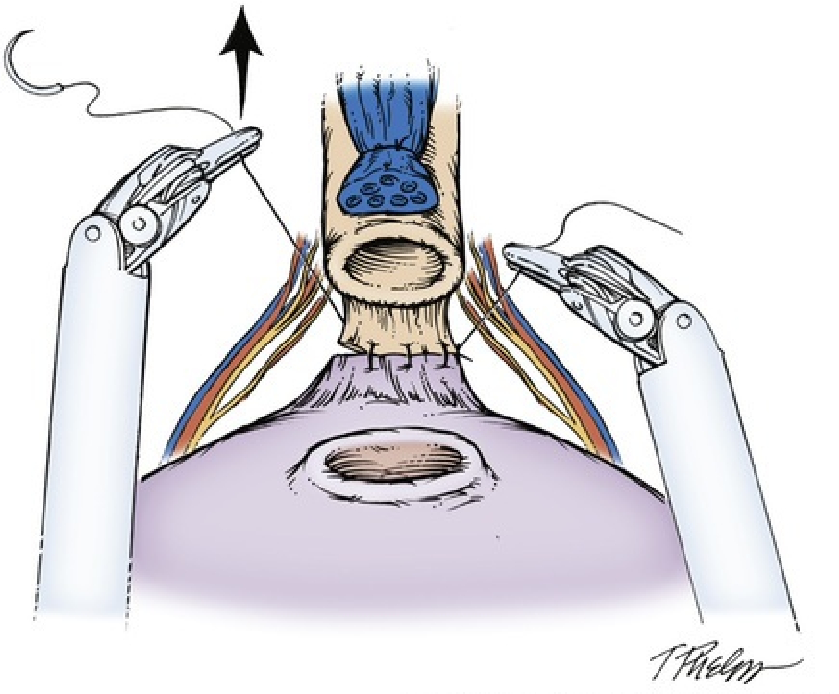

FIG. 156.18 Modified Rocco stitch. Posterior support is provided to the vesicourethral anastomosis by reapproximating the remnant Denonvilliers fascia and posterior detrusor along the posterior bladder neck to the posterior rhabdosphincter using a running continuous 2-0 Monocryl suture. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

Vesicourethral Anastomosis

With LRP, the vesicourethral anastomosis is one of the most technically challenging aspects of the procedure because of the need for laparoscopic suturing. The da Vinci surgical robot greatly facilitates suturing of the anastomosis because of the ergonomics of the wristed robotic instrumentation. Although interrupted sutures may be used for the anastomosis, van Velthoven et al. (2003) described a running suture technique that distributes tension broadly across multiple points along the bladder neck and urethra. Typically, two separate sutures are tied together at their ends, each 6 to 8 inches in length. More commonly, double-armed barbed sutures are used to accomplish this step. The anastomosis between the bladder and urethra begins posteriorly, leaving two needles to run progressively in an anterior direction on either side. **Dedicated**

mucosal eversion sutures at the bladder neck, commonly used during RRP, are unnecessary with the excellent running mucosa-to-mucosa anastomosis achieved with LRP and RALRP. Multiple sutures are first placed through the urethra and bladder before progressive cinching of the anastomosis by lifting each arm of the suture in an anterior direction (Fig. 156.19). Either an assistant or the robotic ProGrasp forceps can be used to grasp one arm of the suture to maintain tension and approximation of the posterior anastomosis while the surgeon reapproximates the contralateral side of the anastomosis using the second suture. The final urethral catheter is passed under direct vision immediately before completion of the anastomosis, and the bladder is irrigated to ensure that there are no leaks. Further interrupted sutures may be required if a leak is identified.

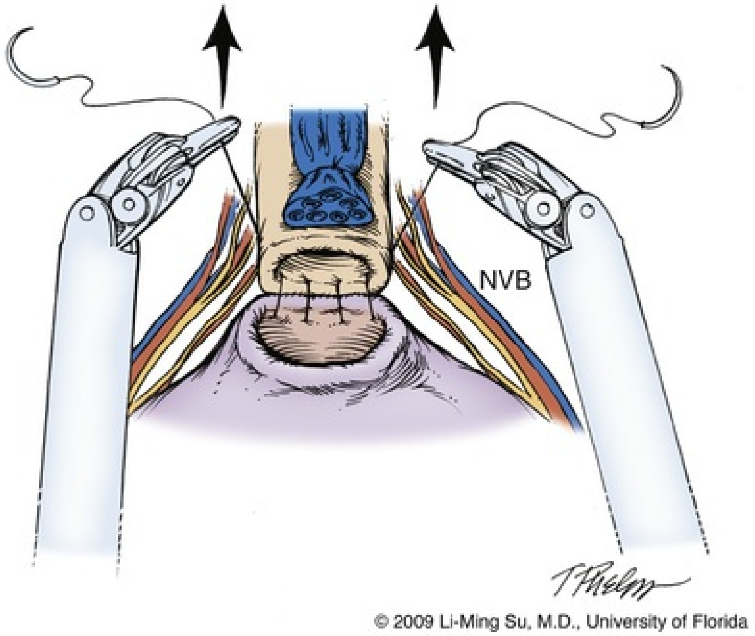

FIG. 156.19 Running vesicourethral anastomosis. The posterior anastomosis is reapproximated after preplacing two or three suture throws on either side starting at the 6 o'clock position and cinching the sutures by lifting anteriorly. Great care must be taken to avoid incorporating the neurovascular bundles *(NVBs)* when placing sutures within the urethra. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

Delivery of the Specimens and Exiting the Abdomen

Before undocking the robot and removal of the specimens, the pelvis and operative field should be carefully inspected for bleeding under low insufflation pressure (<10 mm Hg). The nearby bowel should be examined closely to make certain there is no injury resulting from instrument exchanges. Closure of the fascial defect for the 5- and 8-mm trocar sites is generally not necessary. Because of the potential risk for a trocar site hernia, it is advisable to close the 12-mm trocar sites with a Carter-Thomason fascial closure device (Cooper Surgical, Trumbull, CT). The string for the laparoscopic entrapment sack is transferred to the camera port site at the umbilicus, and the abdomen is completely desufflated. The specimens within the entrapment sack are extracted intact through extension of the umbilical trocar site. The fascial defect is then closed by open suture placement, and the skin defects are closed with a subcuticular absorbable suture.

Key Points: Technique of Laparoscopic and Robotic-Assisted Laparoscopic Radical Prostatectomy

- Use of a transperitoneal or extraperitoneal approach is based primarily on surgeon preference because there does not appear to be a significant advantage of one approach over the other.
- Robotic technology facilitates suturing and dissection for surgeons who may not have advanced laparoscopic skills.
- Identification of the precise margin between the bladder neck and prostate can be accomplished by using a set of physical maneuvers and visual cues.
- After division of the anterior bladder neck, the presence or absence of a median lobe should be defined before division of the posterior bladder neck.
- Complete mobilization of the plane between the posterior prostate and rectum is an important step in avoiding rectal injury and defining the medial aspect of the prostatic pedicles and NVBs.
- Use of thermal energy should be minimized during control of the prostatic pedicles and dissection near the NVBs as thermal energy has been shown to be deleterious to cavernous nerve function in both animal and human studies.
- An interfascial dissection of the NVB is preferred in patients with presumed

organ-confined cancer who desire NVB preservation for potency.

- An anterior or posterior protruding lip of prostate should be anticipated when dividing the prostatic apex from the urethra so as to avoid an iatrogenic positive apical margin.
- Bladder neck reconstruction may be required if there is a size discrepancy between the bladder neck and urethra, especially in patients with prior TURP, a median lobe, or a large prostate gland.
- The vesicourethral anastomosis is most efficiently accomplished with a running continuous suture.

Postoperative Management

Pain Management Post-Prostatectomy

Parenteral narcotic medications may be required for the first 24 hours after surgery but should be used sparingly. Instead, ketorolac may be used in appropriate patients for postoperative pain control. It is relatively unusual for the post-prostatectomy patient to need significant narcotic medications on discharge. A combination of more simple analgesia with acetaminophen or anti-inflammatory medications is generally sufficient in the majority of men following surgery.

Diet

Occasionally after radical prostatectomy, a mild ileus develops that often resolves within 24 to 48 hours. Postoperative narcotic use for pain management can exacerbate this problem and as such should be minimized as discussed earlier. The majority of patients can resume oral fluids and diet within 8 to 12 hours of surgery. Constipation can be a postoperative issue, and the patient should be discharged with advice about minimizing narcotic use and the role of stool softeners.

Deep Venous Thrombosis Prophylaxis

Pneumatic compression stockings are routinely applied at the commencement of surgery and used postoperatively. Subcutaneous heparin, usually administered at the commencement of surgery, also can be instituted until the patient is ambulating. Fortunately, the observed rate of thromboembolic events with minimally invasive prostatectomy is very low.

Pelvic Drain

With the secure and watertight running anastomosis typically achieved, a pelvic drain may not always be necessary. If a drain is placed, it may be introduced through one of the 8-mm robotic trocar sites and does not require a separate stab wound. The drain may evacuate an unanticipated urine leak or lymphatic fluid collection. Often, though, drainage is minimal and the drain typically can be removed on the first or second postoperative day.

Urethral Catheter

The duration of time required for the urethral catheter depends to a great extent on the preferred approach of the surgeon and the extent of bladder neck reconstruction. The 2-week period commonly used with open surgery is generally unnecessary if a watertight vesicourethral anastomosis is achieved. With 1 week or more of an indwelling urethral catheter, the vast majority of patients are able to void adequately with minimal risk for postoperative urinary retention and need for catheter replacement. In these routine cases, a cystogram is generally not required. **The exception, however, is when extensive reconstruction of the bladder neck is necessary (e.g., very large volume prostate gland, large median lobe, post-TURP case) or if there is some doubt about the integrity of the vesicourethral anastomosis. In these circumstances, it may be prudent to leave the catheter for at least 10 days and obtain a cystogram in radiology to confirm the security of a watertight anastomosis.** In cases of extravasation, longer duration of the urethral catheter is required to allow for spontaneous healing. Although this may prolong the time to achieve complete urinary continence, long-term urinary outcomes do not appear to be affected (Patil et al., 2009). To avoid the use of a urethral catheter, some surgeons have investigated the use of suprapubic catheter drainage of the bladder with a specially designed anastomotic splint with good initial results (Tewari et al., 2008).

Return to Normal Activity

Following catheter removal at 1 week, patients spend the next week recovering without particular restriction of activity. Most patients are able to return to all normal physical activity by 4 to 6 weeks. Strenuous exercise can be recommenced at 6 weeks. This is a clear advantage for patients undergoing robotic surgery compared with the open radical prostatectomy technique.

Role of Continence Physiotherapy

It is helpful for the patient to have a session with the specialist physical therapist before the surgery. The patient can be instructed in pelvic floor strengthening with particular emphasis on the external striated sphincter (Centemero et al., 2010). The therapist can use transperineal ultrasonography to help the patient visualize the appropriate musculature to be exercised (Stafford et al., 2014). **There is evidence to suggest that pelvic floor education by physical therapy can shorten the time to recovery of urinary continence** (Overgard et al., 2008; Patel et al., 2013)**. It is therefore important to have the services of a qualified pelvic floor physiotherapist.** The patient is instructed not to commence pelvic floor exercises to strengthen the striated external sphincter muscle for at least 3 days after catheter removal, as early participation in pelvic floor strengthening can cause perineal pain. This can be quite disabling early on. Some men do complain of perineal pain clearly originating from the operative bed for several weeks following catheter removal.

Role of Penile Rehabilitation

Post-prostatectomy erectile dysfunction (ED) is thought to arise from the interaction of three factors: neural injury, vascular injury, and corporal smooth muscle damage (Jenkins and Mulhall, 2016). Recovery is thought to depend on nerve-sparing status, patient age, baseline erectile function, and surgeon experience/volume. Penile rehabilitation programs have been developed in an effort to improve both the time to and degree of erectile function recovery following RALRP.

Most protocols use phosphodiesterase type 5 inhibitors (PDE5Is) as they appear to help preserve erectile tissue through their protective effects on both endothelial and smooth muscle cells. The Memorial Sloan-Kettering Cancer Center (MSKCC) penile rehabilitation program has patients take a low-dose PDE5I nightly starting 2 weeks before surgery and continuing until 2 weeks after RALRP. From weeks 3 to 6, the patient continues the low-dose PDE5I 6 nights a week and takes a maximum dose of a PDE5I once a week. At this point, patients are classified as PDE5I responders or PDE5I failures. Responders continue on PDE5I, whereas failures are started on intracavernosal injection (ICI) therapy or alternative strategies (Jenkins and Mulhall, 2016).

ICI therapy has also been shown to help with recovery of erectile function post-prostatectomy and is often used in patients who do not respond to PDE5Is. In the MSKCC penile rehabilitation program, PDE5I failures start ICI 6 weeks post-prostatectomy. Their protocol has patients perform ICI twice a week and take a low-dose PDE5I nightly on non-ICI nights. Additionally, they challenge themselves with a maximum-dose PDE5I once a month, starting 12 months post-prostatectomy. If they develop a natural response or become PDE5I responders, ICI can be stopped (Jenkins and Mulhall, 2016).

An alternative method that is commonly used in penile rehabilitation protocols is the vacuum erection device (VED). The VED has been used to treat ED for a long time; however, it does not appear to help with the overall penile rehabilitation process, but may help preserve penile length post-prostatectomy (Köhler et al., 2007).

Robotic Prostatectomy Outcomes

Since its introduction into urology in 2002, there has been controversy as to whether RALRP could achieve equivalent outcome in terms of cancer margins, continence, and potency when compared with the standard retropubic open prostatectomy. Many early reports suggested remarkable outcomes of RALRP with regard to potency and continence. These were mostly single-institution reported outcomes. A randomized trial conducted by Yaxley et al. (2016) suggested that outcomes for potency and continence of both robotic and open prostatectomy were equivalent at 3 months. Clearly, the cost of robotic instrumentation and the high capital cost of robotic machines have been barriers to more widespread implementation of robotic surgery (Barbash and Glied, 2010; Barbash et al., 2014).

Studies from Scandinavia comparing individual surgeon outcomes by robotic or open method strongly suggested that outcomes are very dependent on the individual surgeon's ability and experience, and outcomes improve when surgery is performed by high-volume surgeons at high-volume centers (Carlsson et al., 2016; Groeben et al., 2017; Haglind et al., 2015). The study by Yaxley et al. (2016) compared two surgeons, one performing open prostatectomy and the other performing RALRP, in a randomized trial. There was no difference in oncology and continence outcomes, but there was a difference in favor of robotics when blood loss and length of stay were assessed. The advantages of RALRP relate to the minimally invasive nature of this procedure and the ability to obtain at least equivalent outcomes in terms of cancer margins, continence, and potency. Patients undergoing RALRP can return to normal activity more quickly than after open surgery. Furthermore, because of the safety of the minimally invasive approach, more patients can be offered prostatectomy, whereas formerly they were recommended to receive external-beam radiation therapy. Patients in this context are those with previous mesh hernia repair, older patients with medical comorbidities, or those who have had previous abdominal or pelvic surgery.

Complications of Robotic Prostatectomy

Patient Positioning: Neural Injury

Obtaining a thorough history of any preexisting musculoskeletal issues in the preoperative setting is important to help minimize and address these problems in a patient-specific manner. It is important to position the patient on the operating table to prevent excessive neural pressure, particularly cervical, axillary, brachial, and radial. Specific padding needs to be applied to the arms and hands, and care must be taken with the brachial plexus if the arms are extended. Typically, Yellowfins stirrups (Allen Medical, Acton, MA) are used in many operating rooms to protect the legs. The Trendelenburg position used should have between 22 and 25 degrees of tilt. Prolonged operating time in Trendelenburg tilt can cause postoperative edema of the eyes and even sometimes cerebral irritation (Awad et al., 2009). Excessive hip flexion of the operating table should be avoided as this may lead to femoral nerve injury.

Blood Loss/Transfusion

Since the inception of RALRP, many authors have reported a dramatic reduction in blood loss at the surgery compared with the open method (Ficarra et al., 2012a). Most report blood transfusion rates of 1% to 2% after radical prostatectomy (Farnham et al., 2006; Ficarra et al., 2012a). The CO_2 pneumoperitoneum compresses venous bleeding, and the excellent visualization readily allows identification of bleeding vessels requiring hemostasis. In the randomized report from Yaxley et al. (2016), there was a significant difference in blood loss between the open radical prostatectomy and the RALRP surgery. Mean blood loss in the open prostatectomy was 1400 mL, and average blood loss in the robotic cohort was 300 mL.

Bowel Injury

Injuries to rectum, sigmoid, and small bowel are rare but serious complications following RALRP (Kheterpal et al., 2011). If an injury to bowel is recognized at the time it occurs, then that injury can be repaired immediately (Wedmid et al., 2011). Multilayered primary closure of a recognized rectal injury with interposition of omentum between the rectum and anastomosis will usually avoid long-term problems. A rectal injury that is not recognized, however, often presents as a recto-vesical fistula. This will almost always require colostomy diversion. An unrecognized small bowel injury possibly caused by an off-site injury during surgery can be serious. The assistant must be careful to avoid small bowel injury along the path of the multiple instruments that are interchanged and directed into the pelvis during the procedure. The small bowel can also be injured at the commencement of surgery when taking down adhesions. An unrecognized small bowel injury during RALRP can lead to a delay in diagnosis of leakage of small bowel contents. The patient may not present with signs of an acute abdomen and peritonitis. After diagnosis, immediate repair and drainage is generally necessary.

Ureteral Injury

Ureteral injuries are rare during RALRP, with few reports in the literature. Injuries to the ureter can in theory occur during three steps of a RALRP. First, the ureter may be encountered during dissection of the vas deferens during a posterior approach to RALRP. Maintaining close dissection to the adventitia of the vas will help prevent inadvertent compromise to the nearby ureter traveling just posterior to the vas. Second, the ureter may be injured at the level of the trigone (Hu et al., 2006). In cases in which there has been previous TURP, the bladder neck has been obliterated and ureters can be perilously close to the anastomotic site. This is also the case when there is a large median lobe, where a large bladder resection leaves the ureteral orifices in close proximity to the posterior bladder neck edge. In such cases, imbrication of the ureteral orifices before performing the anastomosis may reduce compromise to the ureters as mentioned earlier. Alternatively, a double-pigtail stent can be placed intraoperatively without great difficulty and removed at a later date. Lastly, the ureter may in theory be encountered during dissection of the pelvic lymph nodes. During dissection of the proximal extent of the lymph node packet at the iliac bifurcation, use of thermal energy should be minimized as this may compromise the ureter as it passes over the iliac vessels.

Robotic Machine Failure

Robotic machine failure is a rare event during RALRP. In a study of robotic equipment malfunction encompassing 8240 cases with a mean per-surgeon volume of 700 cases, critical robotic failures occurred in 0.4% cases, leading to a cancellation of 24 cases before the procedure, or conversion to laparoscopic or open procedures in the remainder (Lavery et al., 2008). The most common components of the robot malfunction were the robotic arms and optical system**.** **In conclusion, critical robotic equipment malfunction is extremely rare in institutions performing high-volume RALRP, with a nonrecoverable malfunction rate of only 0.4%.**

Postoperative Complications

Intraperitoneal Urine Leak

If there is a leak from the anastomosis in the immediate post-prostatectomy period, the patient can develop a significant paralytic ileus. If a drain has not been left in place at the conclusion of surgery, a percutaneous drain may be placed by an interventional radiologist to drain any collection. In such cases, a prolonged urethral catheterization can be anticipated in addition to the need for a postoperative cystogram to confirm resolution of the anastomotic leak.

Bladder Neck Stricture

This complication was common following open radical prostatectomy, and there are reports of up to 16% of patients suffering a stricture at the bladder neck following open radical prostatectomy (Breyer and McAninch, 2011). **Since the introduction of RALRP, the incidence of reported bladder neck strictures is low and is less than 2%** (Msezane et al., 2008). The complication is managed by bladder neck incision followed by a period of catheter drainage. Usually this is all that is necessary to restore a satisfactory bladder neck caliber.

Pelvic Node Dissection Complications

The role of pelvic node dissection at the time of radical prostatectomy, limited or extended, remains controversial (Yaxley et al., 2018). It is clear that patients with low-volume primary cancer of low Gleason sum do not require lymph node dissection during prostatectomy. Controversy exists as to whether an extended node dissection in patients with intermediate- or high-risk disease has both a staging and therapeutic benefit. The advent of improved PSMA PET scanning for staging means that many nodes previously not imaged are now seen before surgery. In some patients with advanced local disease, node metastasis is discovered in extrapelvic sites. To date, there has been no study to demonstrate a therapeutic benefit associated with extended pelvic node dissection in high-risk prostate cancer. Pelvic node dissection, however, does carry a risk for morbidity including the development of a postoperative lymphocele, deep venous thrombosis, lower extremity edema, obturator nerve injury, and ureteral injury.

Further details of complications following PLND are discussed later in this chapter.

Quality-of-Life Outcomes After Radical Robotic Prostatectomy

Those surgeons trained in the era of open radical prostatectomy appreciate the dramatic change in outcome for patients undergoing contemporary RALRP. Until Walsh (1980) described a safe technique for open radical prostatectomy in the 1980s, the operation was attended with serious morbidity. Significant blood loss requiring transfusion, a 3-week hospital stay, a 3-week indwelling catheter, almost-certain impotence, and a high likelihood of urinary incontinence was not unusual. The combination of PSA testing with safe open radical prostatectomy meant that many men could now be offered the opportunity for early potentially curative surgery. Robotic radical prostatectomy was first performed in 2000 and became a routine operation within 7 years. Despite the potential and obvious advantages of 12× magnified vision in three dimensions and digitized reproduced hand movements with motion scaling and tremor filter, it was difficult to prove superiority of the robotic technique over the open method. Because of the high capital cost of the robotic machine and disposable instruments, many centers were unable to afford this technology. A technology arms race occurred between centers with and without a robotic surgery platform. Marketing of the superiority of robotic surgery occurred without clear evidence of benefit of the technology. The real benefit of minimally invasive surgery (reduced blood loss, early return to activity and employment, and more favorable outcomes for potency) have since emerged (Costello, 2005). The advent of new, less-expensive versions of robotic surgical technology means that there will be a much greater uptake of robotic surgery, not only for robotic radical prostatectomy, but also other robotic procedures. It has been difficult to perform appropriate randomized controlled studies to prove the superiority of one method over the other. The key outcome measures, or trifecta of outcomes, relate to positive surgical margin rates (oncologic efficacy), postoperative urinary continence, and return of erectile function. Where there have been appropriate comparative studies, RALRP appears superior in returning a higher number of men to previous erectile function (Haglind et al., 2015).

Unfortunately, the adoption of RALRP occurred in the absence of high-level evidence of superiority of robotic technique over open prostatectomy. There were many claims from single surgeons' series of superiority of robotic potency technique and improved potency outcomes (Menon et al., 2005). Claims of near 90% potency from some institutions following robotic radical prostatectomy could not be substantiated in other centers. The Laparoscopic Prostatectomy Robot Open (LAPPRO) study from Scandinavia compared urinary incontinence and ED after open and robotic radical prostatectomy (Haglind et al., 2015). This study was a prospective controlled, nonrandomized cohort of patients undergoing prostatectomy at 14 centers, by either the open or the robotic method. There were 2625 eligible men in the study. In this study, there was a mixture of high- and low-volume hospitals and surgeons to reflect everyday reality. There was no statistically different outcome in reported urinary continence after prostatectomy by either type of surgical technique. There was a statistically significant improvement regarding erectile function after robotic-assisted surgery. The LAPPRO study reports that there appears to be no statistically different outcome in oncologic efficacy of either method (Haglind et al., 2015). Many of the other outcome papers published of RALRP represent single series selected after a long learning curve by a very experienced surgeon. They report excellent outcomes, and this may reflect the fact that the surgeon is now very technically capable (Patel et al., 2011).

What are **true benefits** of robotic radical prostatectomy over open prostatectomy beyond the simple trifecta of margin status, continence, and potency? The clear advantages of the RALRP method relate to the significantly reduced blood loss associated with the procedure as compared with open surgery, next-day hospital discharge, and earlier return to normal activity. In addition, many patients who had previously been considered not suitable for open radical prostatectomy because of issues such as prior mesh hernia surgery, medical comorbidities, morbid obesity, or previous abdominal surgery, are now able to be offered radical prostatectomy.

Functional Outcomes

Urinary Continence After Robotic Radical Prostatectomy

To achieve an optimal outcome for urinary continence following robotic radical prostatectomy, it is important for the surgeon to understand the anatomy of the striated sphincter and the physiologic mechanisms of urinary continence (Koraitim, 2008). Urinary continence has both passive and active components. The passive component is provided by the smooth muscle of the bladder neck, prostatic urethra, and urethra. Thus, when the patient is sitting or lying, passive continence is achieved by the smooth muscle component (Fig. 156.20). When the patient becomes active, the external striated sphincter is activated to angulate the urethra. This is achieved by contraction of the horseshoe-shaped external sphincter skeletal muscle, which surrounds the urethra at the apex (Fig. 156.21). Skeletal muscle of the striated sphincter is composed of fast-twitch fibers. The pudendal nerve supplies this striated external sphincter that surrounds the urethra. The pudendal nerve runs in Alcock's canal. Branches of the pudendal nerve to supply the external sphincter swing from beneath the levator ani muscles into the skeletal muscle of the sphincter at the prostatic apex (Fig. 156.22). There is potential for damage to the pudendal branches when there is excessive dissection, thermal energy, or suturing in this area. The superb visualization provided by the robotic technology facilitates apical dissection and thus preservation of external striated sphincter function.

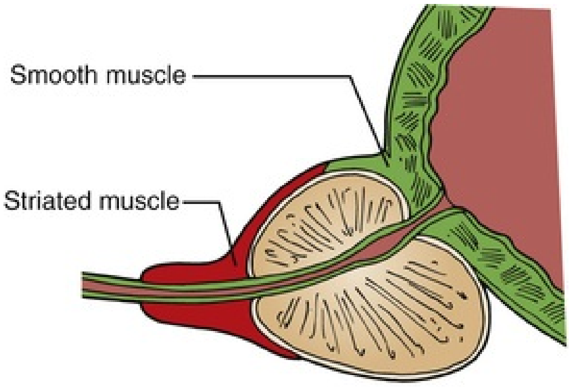

FIG. 156.20 Muscle components of the male urinary sphincter. The passive component of urinary continence is provided by the smooth muscle

(green) of the bladder neck, prostatic urethra, and urethra. The active component of urinary continence is provided by the striated muscle *(red)* of the external urinary sphincter.

Anal sphincter

FIG. 156.21 Schematic of the horseshoe-shaped external urethral sphincter.

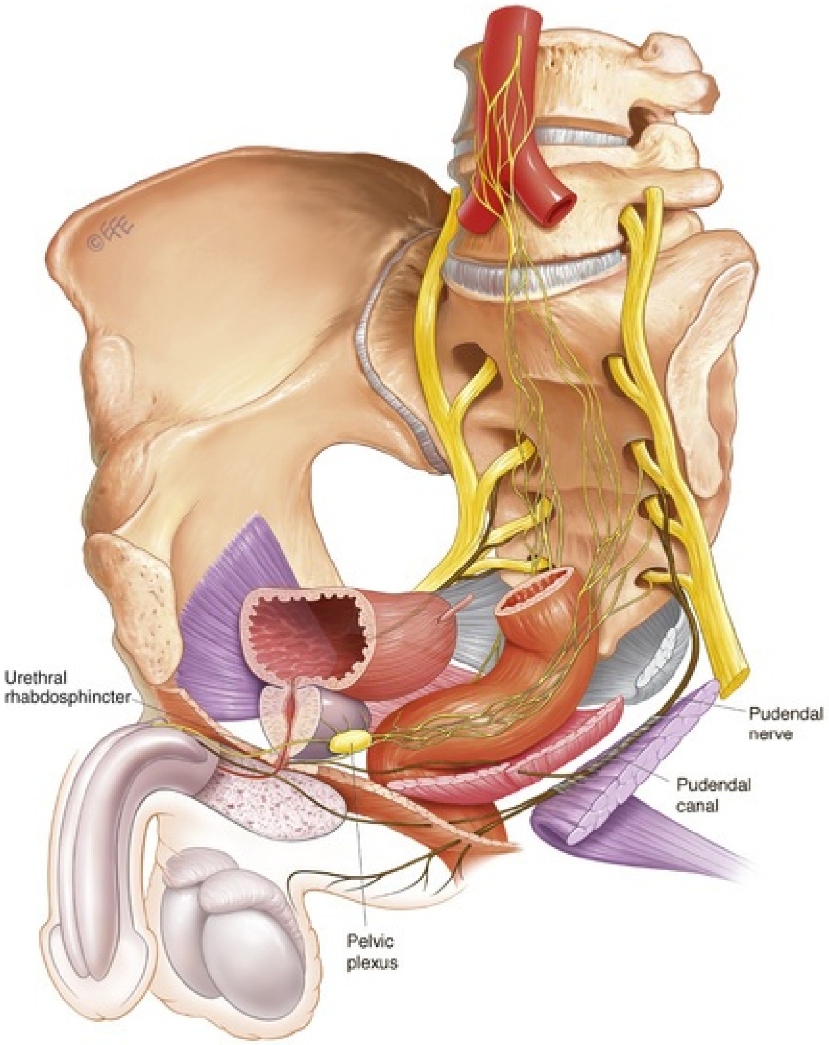

FIG. 156.22 Pudendal nerve innervation of the external urinary sphincter. Note the pudendal nerve branches to the sphincter. The nerve exits through the levator ani and swings close to the prostate near the apex. It is here that the pudendal nerve can be injured during radical prostatectomy.

A problem when discussing continence outcomes with men before RALRP is the variety of definitions of urinary continence and measures used to report continence outcomes following RALRP (Gandaglia et al., 2018). The comparative studies between open and robotic radical prostatectomy have found that 12-month continence outcomes are roughly equivalent. It also must be understood that some men prior to radical prostatectomy have continence issues caused by lower urinary tract obstructive symptoms. From the multiple studies presented, in particular those from community-based practices, the likelihood of developing urinary incontinence requiring use of one or more pads following surgery is 21%. In the LAPPRO study, of the 21% of men requiring pad use following prostatectomy, 13% required one pad every 24 hours and 8% required more than one pad per 24 hours. These results reflect real-world practice and allow the urologist to reliably counsel a man before radical prostatectomy regarding his likelihood of developing urinary incontinence. The more recent advent of suburethral sling surgery has meant that men who are not severely incontinent following robotic radical prostatectomy can be offered restorative surgery to overcome this urinary incontinence (Bauer et al., 2009). In the few men, usually 2% or less, who have severe urinary incontinence (meaning urinary loss of over 500 mL/day), artificial urethral sphincter surgery is beneficial (Van der Aa et al., 2013).

Erectile Dysfunction After Robotic Radical Prostatectomy

Before the anatomic insights into the anatomy of the NVB by Walsh and Donker (1982), impotence following radical prostatectomy was the norm. Further anatomic studies by Costello et al. (2004) demonstrated more clearly the anatomy of the pelvic plexus, NVB, and cavernous nerves (Fig. 156.23). The NVB is made up of a sympathetic neural component via the hypogastric nerve (T12–L1), which joins the parasympathetic component S2–S4 just below the base of the prostate. There is a ganglion below the base of the prostate situated posterolateral to the capsule of the prostate from which the cavernous nerves travel in a separate fascial sheath in most instances. There are nerves to the prostate, seminal vesicle, rectum, and levator ani muscles in separate fascial compartments adjacent to the cavernous nerves. There is a functional organization of the nerves in the bundle running posterolateral to the prostate and anterolateral to the rectum. These nerves run in a separate fascial compartment outside the capsule of the prostate (see Fig. 156.14). Identification of the NVB at the time of RALRP and meticulous dissection of this group of nerves is critical in preservation of potency. At the prostatic apex, cavernous nerves swing medially and anterior to about the mid-urethra and the 3 o'clock and 9 o'clock positions. **It is here during apical dissection when it is most likely that the neurovascular component of erectile function can be damaged** (Fig. 156.24). There is a separation of 3 to 5 mm between the NVB and the capsule of the prostate. This means that **most men being operated on for *localized* prostate cancer can be offered nerve-sparing surgery.** In some cases, where there have been extensive preoperative biopsies or multiple biopsies particularly by the transperineal route, scarring at the apex occurs, making the apical dissection more difficult and more likely that there will be damage to the cavernous nerves at this point. In men with locally extensive disease outside the capsule of the prostate that is palpable on digital rectal examination preoperatively, it may be necessary to perform a wider dissection and sacrifice one or both NVBs.

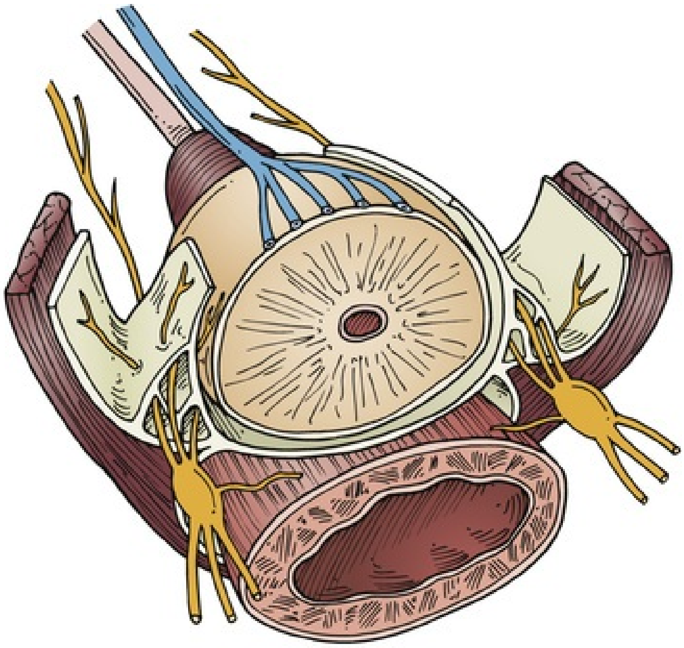

FIG. 156.23 Neurovascular bundle anatomy. There is a functional organization of the nerves in the bundle running posterolateral to the prostate and anterolateral to the rectum. These nerves run in a separate fascial compartment outside the capsule of the prostate.

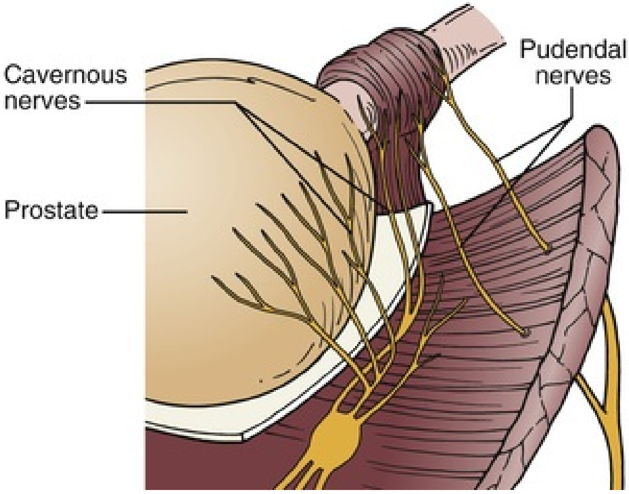

FIG. 156.24 Relationship of neurovascular bundle to the apex at the time of radical prostatectomy.

The development of ED after radical prostatectomy remains one of the most challenging side effects of the operation. Reporting of this complication following radical prostatectomy is bedeviled by a multiplicity of outcome measures used to assess erectile function. In fact, many men 60 years of age and older have preexisting ED before their radical prostatectomy surgery. Younger men, those in their 40s and early 50s, generally have better erectile function before surgery and are more likely to recover function than older men (Ficarra et al., 2012a). Many reports of outcomes following radical prostatectomy failed to acknowledge the use of PDE5Is or intracavernosal injections to aid in restoration of function. It is also well recognized that erectile function can return up to 5 years after surgery, and a 12-month ED definition point is possibly too early to assess eventual outcome. From the Scandinavian and other studies, it is clear that NVB is very surgeon-dependent, and some surgeons are able to achieve more favorable outcomes than others in terms of potency preservation (Carlsson et al., 2016). Reliable outcome data from Scandinavia suggest that a reasonable expectation of return to erectile function in a previously potent man will be between 30% and 50% (Carlsson et al., 2016). **When RALRP is performed in high-volume centers, more favorable potency outcomes are reported** (Patel et al., 2011).

Oncologic Outcomes of Robotic Radical Prostatectomy

Oncologic outcomes after radical prostatectomy are evaluated by assessment of margin positivity and late biochemical recurrence with elevation of PSA following prostatectomy above 0.1 ng/mL. An extensive systematic review and meta-analysis of studies of reported oncologic outcome after RALRP by Novara et al. (2012) showed no difference in positive surgical margin rates between open radical prostatectomy and RALRP. A further study has supported this finding (Coelho et al., 2010). These authors reported a 7-year biochemical recurrence-free survival rate after RALRP around 80% (Novara et al., 2012). Meaningful cancer-specific survival rates need to be assessed at 15- to 20-year intervals from prostatectomy.

Surgical margin status after radical prostatectomy has often been used as a surrogate measure of surgeon performance. **It is clear that in centers where a high volume of robotic radical prostatectomy cases are undertaken, positive margin rates are less than in lower-volume community centers.** However, even in centers of excellence, there is heterogeneity of outcomes for positive surgical margins, with individual surgeons demonstrating different positive surgical margin rates (Haglind et al., 2015). Higher Gleason score and tumor stage are key factors in margin positivity. Tumor characteristics such as Gleason grade 7 or above, perineural invasion, and high tumor stage are all associated with higher levels of margin positivity. Interestingly, factors such as obesity with high BMI, large prostate volume, and prior abdominal surgery do not increase positive surgical margins (Coelho et al., 2010; Khaira et al., 2006). Zorn et al. (2009) compared oncologic outcomes of 60 robotic prostatectomies performed by two fellowship-trained urologists to the outcomes of 90 robotic prostatectomies performed by three open surgeons adopting RALRP. This comparison showed that 3-month PSA recurrence was higher for patients operated on by the non–fellowship-trained surgeons (10%) as compared with the fellowship-trained surgeons (2%). Zorn et al. also demonstrated that the risk for biochemical recurrence remained stable over 700 cases after the learning curve of the operation was overcome. Novara et al. (2012) reported in a meta-analysis, after reviewing 79 papers, a mean positive surgical margin rate of 15% in all-comers, and 9% positive margin rate in pathologically localized cancers, with specific tumor characteristics being the most relevant predictors of positive surgical margins.

In conclusion, positive surgical margin rates are similar following open radical prostatectomy and RALRP. Positive margin rates and biochemical recurrences are lower in centers with high-volume surgeons and where

RALRP is performed. Fellowship-trained surgeons perform better than those who are not fellowship-trained. There is heterogeneity of outcome between surgeons, even in centers of excellence.

Key Points: Complications and Outcomes of Robotic-Assisted Laparoscopic Radical Prostatectomy

- **Patient positioning:** Care must be taken when positioning in the Trendelenburg position that any potential area of neural compression is padded.
- **Blood loss:** Blood loss of robotic prostatectomy is usually minimal, and transfusion requirements should be less than 2%.
- **Bowel injury:** Injury to the rectum is well reported but rare, and should be repaired when recognized. The rectal injury rate is higher in salvage surgery.
- **Urine leak:** This occasionally occurs through a nonwatertight anastomosis and requires a longer urinary catheter period.
- **Bladder neck stricture:** The occurrence of bladder neck stricture is much reduced since the introduction of robotic anastomotic technique. The rate should be less than 5%.
- **Machine failure:** Machine failure is rare and affects less than 0.5% of cases.
- **Oncologic outcomes:** There is equivalence in oncologic outcomes between robotic and open radical prostatectomy. The robotic oncologic outcomes (margin negative) are better when surgery is performed in a high-volume center.
- **Potency outcomes:** There is a statistically more favorable outcome for potency recovery following robotic prostatectomy versus the open method.
- **Continence outcomes:** Even in the best hands, at least 20% of men following robotic prostatectomy will not be pad free, and 5% will have severe incontinence irrespective of technical excellence.
- **Minimally invasive surgery outcomes:** After robotic prostatectomy, patients can be discharged in 24 hours and return to normal activity within 3 weeks. This is a significant advantage of the minimally invasive surgical

approach.

Salvage Robotic-Assisted Radical Prostatectomy

After introduction of RALRP, there has been increased usage of the technique after failure of localized therapies. These therapies include external-beam radiation therapy, seed brachytherapy, high-intensity focused ultrasonography (HIFU), and cryotherapy (Stephenson and Eastham, 2005). Before the introduction of RALRP, most surgeons were not comfortable offering salvage radical prostatectomy by the open method after failure of external-beam radiation therapy or brachytherapy. The reason for a reluctance to surgically intervene after failure of these therapies was the reported high incidence of complications, particularly urinary incontinence, ED, bladder neck stenosis, and rectal injury. The incidence of rectal injury during salvage prostatectomy has been reported to be more than 15% at some centers (Philippou et al., 2016). Although it has been reported that salvage robotic-assisted radical prostatectomy incurred a higher rate of complications, recent reports suggest that outcomes show this is still a feasible procedure (Philippou et al., 2016). The improved visualization afforded by the robotic technology allows the surgeon precise dissection technique in the presence of significant fibrosis caused by these therapies. The stage-specific 5-year cancer control rates of salvage radical prostatectomy are equivalent to those of the author's standard open radical prostatectomy. When offering the patient salvage RALRP following failed external-beam radiation therapy, brachytherapy, HIFU, or cryotherapy, establishing biopsy-proven persistence or recurrence of cancer is imperative as is a full metastatic workup to exclude occult metastatic disease. A fluciclovine F18 PET scan is especially beneficial to assess the possibility of disease outside of the prostate gland region. The PSA should ideally be lower than 10 ng/mL. These cases are perhaps best performed at high-volume centers by experienced robotic surgeons as they can be very challenging.

Salvage Prostatectomy Technique

Development of the extraperitoneal space along the pelvic sidewall, as well as the space of Retzius, can be more difficult in patients previously treated with external-beam radiation. Caution must be used in dissecting the bladder from the iliac vessels because of the desmoplastic reaction that is often encountered. These tissue planes typically are preserved in patients who received brachytherapy, cryotherapy, or HIFU.

Incision of the endopelvic fascia is performed to help identify the contour of the prostate. Suture control of the DVC may sometimes be unnecessary as an initial step because clear identification of the prostatic apex can be difficult at this point, and only minimal back bleeding occurs because of radiation effects. The bladder neck is identified primarily by exposing the lateral margins of the prostate and performing a pinch maneuver with robotic instruments to demonstrate the prostate bladder neck junction. The bladder neck may be pale and thickened. Complete dissection of the seminal vesicles should be performed, because the incidence of invasion is higher in these patients with recurrent prostate cancer.

Even though there is typically fibrosis surrounding the entire prostate in a salvage setting, the posterior dissection can be particularly difficult because of the periprostatic inflammation and scarring as a result of prior local therapy. The plane posterior to Denonvilliers fascia is where rectal injury can occur. As such, patients who are candidates for salvage prostatectomy are advised to undergo a full mechanical bowel preparation before surgery in the event that a rectal injury occurs. The perirectal fat plane is dissected along the anterior rectal wall with patience and great care so as to minimize the risk for rectal injury. Robotic technology provides a distinct advantage over the open approach in salvage prostatectomy with much better visualization in the performance of an antegrade release of the rectum from the posterior prostate. The plane is developed with sharp and blunt dissection. If brachytherapy has been used, the brachytherapy seeds are encountered here, although they can be found during the dissection at any stage of the surgery. The rectum should be carefully inspected after removal of the prostate. An air bubble test can be performed to localize a small rectal injury that is suspected but not visually apparent. A rectal injury can be repaired primarily, but it is essential to perform a two-layered closure that is secure. The omentum may be mobilized to interpose between the bladder and rectum. If there is any doubt about the quality of rectal repair, intraoperative consultation with a colorectal surgeon with consideration of a colostomy should be performed.

The anastomosis is performed in the same running fashion as for those patients who have had no prior therapy. However, these patients are at higher risk for urinary extravasation at the anastomosis, and later for bladder neck strictures, because of the radiation effect or fibrosis effect from these other therapies. The urinary catheter should be left in place for 3 weeks in these patients because of delayed healing of previously treated tissue. A cystogram should be strongly considered before catheter removal to ensure watertight closure.

There is a higher rate of urinary incontinence following salvage prostatectomy as compared with RALRP performed in the primary setting, with between 50% to 70% of patients regaining reasonable continence (Stephenson and Eastham, 2005). Nerve sparing is technically difficult because of extensive periprostatic scarring, and the patient is most often impotent after this procedure. It should be noted that most patients suitable for salvage prostatectomy are more likely to have existing ED resulting from the prior treatment. In any case, realistic expectations of significant postoperative ED should be made in the preoperative counseling session.

Minimally Invasive Pelvic Lymph Node Dissection

Indications

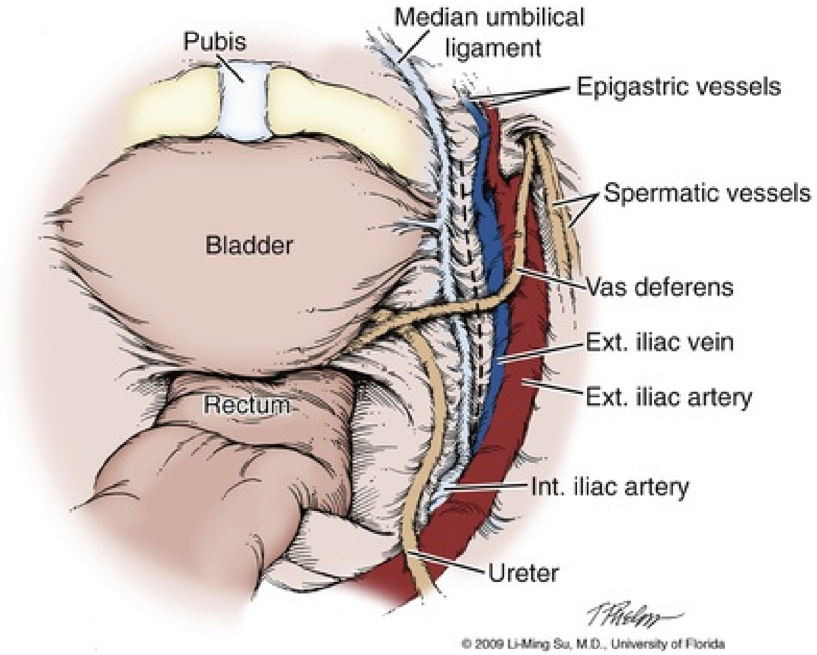
Currently, PLND is rarely indicated as an independent staging procedure. In some patients with a significant risk for nodal metastasis, such as those with a high Gleason grade tumor, a large tumor volume, or a markedly elevated PSA level, PLND may be useful for staging and selection of therapy before external-beam radiation. Also, staging PLND may have a role in some patients in whom radical perineal prostatectomy is planned. With RRP, LRP, or RALRP, it is the usual practice that PLND be performed simultaneously with the radical prostatectomy.

Expert opinion about the role of PLND in patients undergoing surgery for carcinoma of the prostate continues to evolve. **Current debate centers around the anatomic boundaries for the procedure, the merits of an extended lymph node dissection, and whether there is any meaningful therapeutic benefit to surgical removal of involved nodes.** Several different anatomic templates have been studied. A limited PLND generally includes only the obturator nodes; a standard PLND (sPLND) includes the obturator and external iliac nodes; an extended PLND (ePLND) includes the obturator, external, and internal iliac nodes; and a superextended PLND includes the ePLND template plus common iliac and presacral nodes (Fossati et al., 2017). A template mapping study found that using a sPLND template would capture 38% of the lymph nodes that drain the prostate, an ePLND template can capture 63% of these lymph nodes, and including the common iliac nodes can increase this to 75% (Mattei et al., 2008). **As such, most contemporary thought and evidence supports an extended node dissection in cases in which node dissection is indicated. The rationale for this approach is a significantly higher yield of nodal tissue and identification of nodal metastasis with extended versus a standard dissection.** With respect to the therapeutic benefit of PLND, a systematic review found conflicting results with respect to biochemical and clinical recurrence, with no significant improvements in cancer-specific or overall survival, while also observing increased operative time, blood loss, length of stay, and postoperative complications as the extent of the PLND increased (Fossati et al., 2017). Despite these findings and given the overall low quality of data on this subject, the authors concluded that PLND remains justified as it is our best method of assessing for nodal metastasis at this time.

Most studies show histologic evidence of nodal metastasis in less than 5% of patients with low-risk features in the primary tumor. Consequently, PLND may not be required in patients with low-risk prostate cancer. **The 2017 Clinically Localized Prostate Cancer: AUA/ASTRO/SUO guideline states that pelvic lymphadenectomy can be considered for any localized prostate cancer patient undergoing radical prostatectomy and is recommended for those with unfavorable intermediate- or high-risk disease** (Sanda et al., 2018)**. The European Urology Association recommends an extended lymph node dissection in all patients with a risk for nodal metastasis greater than 5% based on preoperative risk nomograms that utilize an extended PLND template (Briganti nomogram, MSKCC, or Roach formula)** (Mottet et al., 2017)**.**

Surgical Technique

In laparoscopic staging PLND, trocar configuration is similar to that for LRP and RALRP, but only one assistant trocar is generally necessary. Abdominal access is established, and an incision is made just lateral to the medial umbilical ligament back toward its confluence with the hypogastric artery and down to the pubis (Fig. 156.25). Great care must be taken to avoid injury to the nearby ureter. If PLND is performed during LRP or RALRP, the dissection is simplified because previous mobilization of the bladder provides excellent exposure of the obturator space.



Pubis
Median umbilical ligament

FIG. 156.25 Laparoscopic pelvic lymph node dissection. Initial transperitoneal view of the obturator fossa and relevant anatomy. The *dashed line* indicates the longitudinal incision that is made in the peritoneum lateral and parallel to the median umbilical ligament back toward the bifurcation of the iliac vessels in effort to provide exposure to the obturator fossa and lymph nodes. *Ext.,* exterior; *Int.,* interior. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

As with an open approach, a key initial step to standard laparoscopic PLND is separation of the nodal packet from the external iliac vein. The lymph node packet is grasped and retracted medially. A relatively avascular plane between the lymph node packet and lateral pelvic sidewall is identified and can be dissected bluntly. Dissection is carried out proximally to the iliac bifurcation and distally to the pubis, thus defining the lateral extent of the lymph node packet. By retracting the lymph node packet medially, the precise course of the obturator nerve and vessels can be identified and protected (Fig. 156.26). After securing the distal extent of the lymph nodes with hemoclips, the packet is divided, retracted cranially, and bluntly separated from the obturator vessels and nerve by blunt dissection. Hemoclips are again placed on the proximal extent of the lymph node packet (Fig. 156.27). Further dissection of the neighboring lymph nodes is performed based on the desired template (i.e., sPLND vs ePLND). The lymph nodes usually can be removed as a single packet and extracted either through the 12-mm trocar or by placing them in the entrapment sack along with the prostate specimen.

FIG. 156.27 Final dissection of a standard pelvic lymph node template. The proximal and distal extent of the lymph node packet are clipped and divided, taking great care to avoid injury to the obturator nerve and vessels, as well as the accessory obturator vein. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

Some controversy remains about the precise anatomic boundaries of an extended node dissection for patients with prostate cancer; however, an ePLND is now generally recommended (Mottet et al., 2017). **Commonly, though, the boundaries are 2 cm cephalad to the bifurcation of the common iliac artery at the point where the ureter crosses over the vessels and distally to the node of Cloquet. The lateral margin should be the genitofemoral nerve, and the medial border is the bladder wall. Complete removal of all nodal tissue surrounding the obturator nerve is essential, and the bladder pedicle should be skeletonized. Presacral nodes often are included with a superextended dissection.** Extended lymph node dissection can be performed laparoscopically and robotically. The da Vinci Si system allows more proximal angulation of the instruments, and this can significantly facilitate dissection around the bifurcation of the common iliac artery. A thorough dissection adds time to the surgical procedure, but this is true regardless of whether laparoscopic, robotic, or open surgery is performed.

No valid comparative studies exist to support the superiority of open versus laparoscopic PLND. Using lymph node count as a surrogate for adequacy of the dissection is problematic because the method and thoroughness of pathologic evaluation is perhaps even more influential than the anatomic extent of the surgical dissection. With careful attention to meticulous dissection, though, all of the fibrous, fatty, and lymphatic tissue within the commonly accepted anatomic boundaries for an extended lymph node dissection can be removed laparoscopically or robotically. Use of clips on identifiable lymphatic channels can minimize the occurrence of a postoperative lymphocele.

Complications

In 2013, Van der Poel et al. reported a 14.1% overall complication rate in 440 patients undergoing PLND. Because, by definition, PLND requires skeletonization of portions of the common iliac, external iliac, and hypogastric arteries and veins, the possibility of major vascular injury exists. A small venotomy or arteriotomy can be closed laparoscopically or robotically with a fine polypropylene (Prolene) suture. A major injury may require rapid conversion to an open approach. However, the incidence of major vascular injury resulting in enough bleeding to require transfusion is well under 1% with PLND.

Transection of the obturator nerve may occur, leading to loss of sensation in the medial thigh and difficulty with adduction of the leg. Direct repair with suturing of the ends of the obturator nerve using a fine polypropylene suture can restore partial function. Ureteral injury is uncommon, but caution must be observed during the proximal portion of the dissection as the ureter crosses the anterior portion of the common iliac artery.

The major complication of pelvic node dissection relates to the development of postoperative lymphocele. **Theoretically, the communication with the entire peritoneum would allow distribution and absorption of any lymphatic fluid throughout the peritoneal lining of the abdomen and decrease the risk for lymphocele. Despite this, however, a loculation of lymphatic fluid can occur. As such, a transperitoneal RALRP approach is not protective against the formation of a postoperative lymphocele. Lymphocele is the most common complication of PLND and has been reported to occur in up to 60% of patients.** However, the clinically significant lymphocele rate is reported between 2% and 5% (Ploussard et al., 2014). Asymptomatic lymphoceles do not necessarily require drainage or treatment. A larger collection can compress the bladder and cause new-onset or worsening irritative voiding symptoms. Compression of the external iliac vein can predispose a patient to DVT in the lower extremity. Secondary infection of lymphoceles also may occur. In the presence of symptoms or complications from a lymphocele, temporary placement of a percutaneous drain with or without injection of a sclerosing agent is typically successful. However, lymphatic fluid can reaccumulate, requiring repeat drainage with injection of a sclerosing agent or surgical opening of a window with marsupialization of the lymphocele wall by laparoscopic means. Late development of bilateral leg edema is rarely seen after some cases (Musch et al., 2008).

Key Points: Minimally Invasive Pelvic Lymph Node Dissection and Complications

- PLND is generally recommended in patients with intermediate- or high-risk prostate cancer or those with a greater than 5% risk for nodal metastasis using a clinical nomogram.
- Although an extended PLND may yield a higher lymph node count, debate continues as to the extent of PLND and the clinical benefit of removing cancerous nodes given the increased time and complication rates.
- Use of clips on identifiable lymphatic channels can minimize the occurrence of postoperative lymphoceles.
- A transperitoneal approach is not protective against the formation of a lymphocele because loculation of lymphatic fluid can still occur within the peritoneal cavity.
- Symptomatic lymphoceles, which cause local problems such as venous or bladder compression, may require percutaneous or laparoscopic drainage.

Genomic Research on Fresh Prostatic Cancer Tissues and Tissue Banking

In centers where research on prostate cancer is performed in association with high-volume radical prostatectomy programs, prostate cancer tissue is available for genomic research. Although DNA can be extracted from formalin-fixed tissue, ideally fresh prostate cancer tissue is best for genomic research. Kerger et al. (2012) described a technique to identify by frozen section the index cancer, which is then preserved in liquid nitrogen. Aggregation of this tissue in biobanks is then possible, which can be matched to patient informatics. Subsequently, patients who have had their primary prostate cancer removed and banked and who have developed bone metastases can consent to biopsy of the bony metastasis. Thus a linear history of the mutational ability of an individual cancer can be mapped.

Future of Robotic Surgery

Rassweiler et al. (2017) recently described the numerous new robotic systems that will be available after the relevant patents for the first-generation da Vinci platform expire in 2019. **Several new console-base robots for laparoscopic multi- and single-port surgery will come to market in the coming years. One example of a single port platform that is now available is the da Vinci SP system. There will be significant differences in the features of the new robotic machines. There will be a variety of instrumentation, consoles, and video technology**. Clearly the da Vinci systems have set a high bar of engineering excellence that other competitors will find difficult to match. However, cost reduction will likely permit more widespread uptake of new robotic platforms. We have entered the second generation of robotic surgical technology.

The advent in 2018 of less-expensive robotic technology will mean broadening of the patient base being offered this surgery. The major concern in application of robotics has been the economic cost burden. The availability of modular robotic systems with equivalent instrumentation costs to laparoscopic surgery will allow for wide dissemination of robotic through pelvic and abdominal surgery. Medtronic Surgery, Cambridge Robotic Systems, and a number of other vendors are entering the market in robotic surgical technology. In urologic surgery beyond radical prostatectomy, other applications of robotics will include pyeloplasty, partial nephrectomy, and radical cystoprostatectomy. **This broadening of robotic surgery beyond radical prostatectomy will mandate the embedding of a robotic surgery curriculum in all urology residency and fellowship training programs.** Appropriate simulation and virtual reality systems will need to be employed in the teaching curriculum (Ficarra et al., 2012b).

Summary

RALRP has now become the operation of choice for both localized and even locally advanced prostate cancer. Open radical prostatectomy is now uncommonly performed in the United States. There has been wide dissemination of RALRP in Europe and throughout Asia. The robotic technology vision system and superb laparoscopic instrumentation provide clear advantages to patients undergoing this procedure. These advantages relate to minimally invasive surgery in a 12× magnified operative field in three dimensions. This allows the procedure to be performed as an overnight stay case, with much earlier return to normal activity as compared with open surgery. There is now evidence to demonstrate equivalence in oncologic and urinary continence outcomes and improved outcomes with regard to erectile function. Implementation of robotic technology in surgery has allowed more patients to be offered surgery as a choice of treatment for localized prostate cancer, and in the salvage prostate cancer surgery setting.

Cost still remains an issue with this technology. The entry of new vendors with alternative robotic platforms with a lower cost base promises wider implementation of robotics beyond radical prostatectomy. Dissemination of robotic technology in surgery will mandate a significant change in approach to surgery training and in particular urology residency training. There is now the ability to teach robotic surgery with virtual reality and simulation away from the operating room. Urology residents can be monitored during performance of repetitive tasks evaluable by mentors. This training can then take place before the performance of live surgery on patients in the operating room (Ficarra et al., 2012b). This may make robotic surgery training more analogous to aviation education with improved communication and operating room safety.

Radiation Therapy for Prostate Cancer

Ryan Phillips MD, PhD, Sarah Hazell MD, Daniel Y. Song MD

Historical Perspective and Technological Advances

Wilhelm Conrad Roentgen is generally credited with the first description of what he called “x-rays” when in 1896 he presented a lecture entitled “Concerning a New Kind of Ray.” His work led to the rapid emergence of the study of diagnostic radiology and earned him the first Nobel Prize in Physics in 1901. Shortly thereafter, radiation was also being utilized to treat a variety of skin diseases, including cancer (n.a., 1983). However, it took several more decades and the discovery of deoxyribonucleic acid (DNA) before it was understood that the primary mechanism for the effect of radiographs on tissues was via ionization and production of DNA damage, either directly or via free radical production.

The first documented radiotherapeutic approach to treatment of prostate cancer was by Pasteau and Degrais in 1911, who described using an intraurethral radium source, with modifications of this approach later utilized by Young and Fronz in 1917.

There are reports of external beam radiotherapy (EBRT) using kilovoltage radiation for the treatment of prostate cancer between 1930 and 1955 (Attwater, 1930; Hultberg, 1946). However, a problem inherent to kilovoltage radiation is a high deposition of dose at the skin, limiting the ability to deliver tumoricidal doses of radiation to the prostate because of unacceptable skin and normal tissue toxicity. Further technical advances would be required before RT could achieve greater efficacy and safety. Several relevant considerations exist when delivering therapeutic radiation, particularly in a relatively deep-seated internal organ such as the prostate:

1. Need for tissue penetration of beams with minimal energy deposition to superficial structures to reduce skin and tissue toxicity
2. Proximity of and need for sparing of adjacent normal tissues such as the rectum, bladder, and femoral heads
3. Minimizing the potential for targeting errors resulting from organ motion and tissue deformation

The need to overcome these issues led to the improvements that occurred over subsequent years and resulted in the modern techniques available today.

High-Energy Linear Accelerators

Following the development and availability of high-energy megavoltage radiation therapy (RT) units in the 1960s, definitive treatment to the prostate could be delivered without severe damage to normal structures because of superior tissue penetration and reduced skin doses (Bagshaw and Kaplan, 1962). Linear accelerators function by accelerating charged particles (usually electrons) to high speeds using a series of oscillating electric potentials along a linear beamline. The electrons strike a target (typically tungsten) that then produces **photons** (x-rays). The photon beam can then be shaped using variable collimators or tungsten “leaves” within the machine before exiting to the patient (older units used custom-cut lead blocks). The physical property that permits the photon radiation generated from a linear accelerator to penetrate deeply and spare normal tissue is high-beam energy. As the energy of the beam increases, the beam penetrates deeper before exerting its cytotoxic effect. Whereas older orthovoltage (100 to 500 kilovolts) and cobalt-60 units (1.17 to 1.33 megavolts) deposited their maximum dose at approximately 1.25 cm below the skin surface, modern high-energy linear accelerators (6 to 15 megavolts) deliver the maximum dose of radiation at 15 cm or more below the skin surface.

Further significant advancements in the radiotherapeutic management of prostate cancer occurred in the early 1980s and 1990s. The first was the development of more conformal techniques capable of delivering higher doses of radiation deep within the pelvis while simultaneously respecting the radiation tolerance of the anterior rectal wall, prostatic urethra, femoral heads, and bladder neck. This period was notable for the development and widespread adoption of CT-based, three-dimensional conformal radiotherapy (3D-CRT), followed by intensity-modulated radiation therapy (IMRT).

CT-Based Treatment Planning and Three-Dimensional Conformal Radiotherapy

Early radiation oncologists had to treat cancers without precise knowledge of their location within the body. Knowledge of normal anatomy, routes of spread of a particular cancer, and limited information from diagnostic radiology were used for treatment planning (Asbell et al., 1980). Radiation oncologists became adept at designing radiation fields on the basis of skeletal anatomy. For the treatment of prostate cancer, the radiation portals were centered near the pubic symphysis and femoral heads. The location of the prostate was often inferred indirectly by introducing a contrast-filled Foley catheter and rectal tube into the patient and obtaining orthogonal x-ray images. These techniques were employed as recently as the mid-1980s. In this era before computed tomography (CT), radiation treatment technique was sometimes referred to as **conventional radiation.** Clinicians knew as early as 1980 that they were potentially making significant errors in field placement without CT data, but limitations in computer hardware and software allowed no solution to the problem (Fraass, 1995; Rosenman et al., 1991). They also knew that radiation doses received by surrounding organs caused morbidity, but lacked accurate methods for calculating doses received by these organs, and typically would rely on calculations of dose to one or two particular points projected to be within the organ of interest.

The ability to visualize the prostate during radiation treatment planning arrived in the 1990s with the advent of CT scanners and use of CT for radiation planning. This was a dramatic breakthrough in radiation treatment for prostate cancer, because it allowed the ability to design radiation beams to directly target the prostate and for the first time accurately calculate doses received by nearby organs such as the rectum and bladder (Mohan et al., 1992; Niemierko et al., 1992). Radiation penetration and dose deposited within tissues is generally a function of electron density, which varies most significantly among bone, air, and soft tissues. The combination of widespread CT availability and computers with improved graphics and computational power significantly changed the field of radiation oncology by allowing better tissue delineation and advanced dose computation that accurately accounted for tissue inhomogeneities.

With modern CT-based treatment planning, the treatment process is initiated by having the patient scanned with CT in the treatment position to be utilized for daily treatment, a procedure called ***simulation***. The imaging data are then transferred to a treatment-planning system which allows the radiation oncologist to delineate the target volume (i.e., the prostate) and relevant normal tissues (otherwise known as ***regions of interest***, *or* ***ROIs***). The radiation oncologist determines and prescribes the dose of radiation to be delivered to the target (and acceptable degree of variation within the target volume) and the constraints on the amount of radiation the relevant normal tissues can receive without undue risk for toxicity. Under the radiation oncologist's supervision, medical dosimetrists and physicists use the treatment-planning system to define, calculate, and optimize the treatment beams or arcs to achieve the desired dose to the target volume while maximally sparing other tissues. Doses received by the delineated tissues/tumor can be represented graphically using a **dose-volume histogram (DVH),** which plots the dose received by varying volumes of the target and the normal tissues/organs. An example is **IMRT.** An IMRT dose-volume histogram is shown in Fig. 157.1. Using CT, the prostate and surrounding structures could be identified with increased precision, and the beam's-eye view, a technique allowing visualization of the regional anatomy from the perspective of the beam apertures, enabled the design of plans that could more accurately treat the prostate target while minimizing dose to the surrounding normal tissues using custom beam shaping. The result is described as 3D-CRT because the radiation beams conform to the shape of the treatment target (Fraass, 1995).

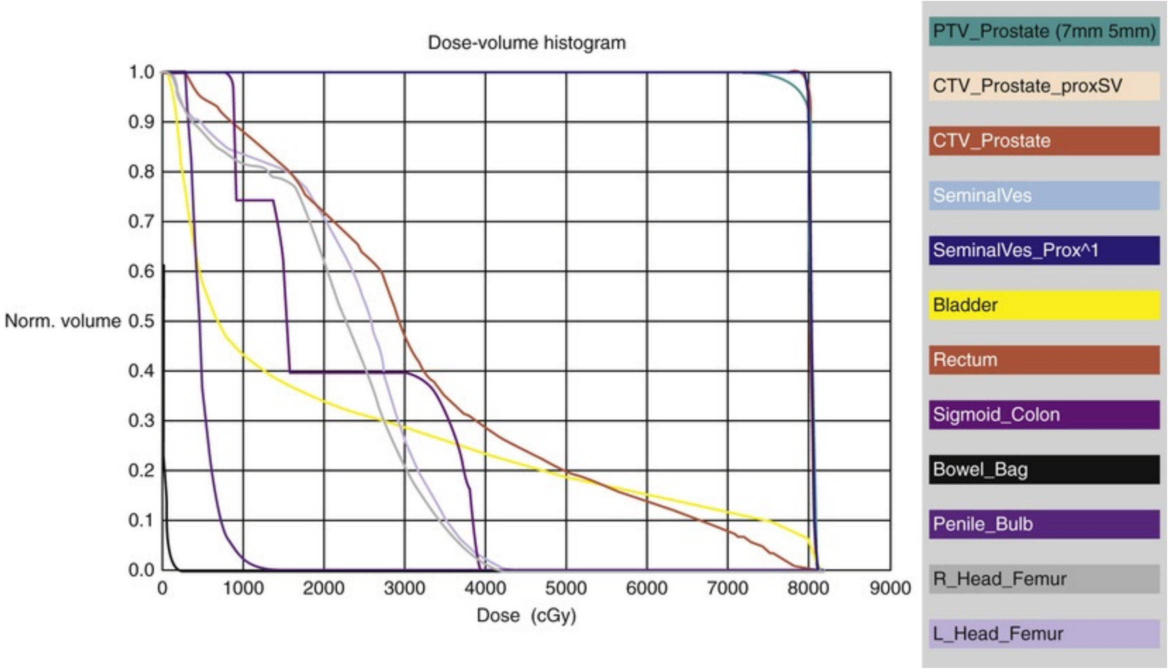

FIG. 157.1 Dose-volume histogram (DVH) of conventionally fractionated, intensity-modulated radiation treatment plan. Both volume (*y*-axis) and dose (x-axis) are typically evaluated and shown as percentages of total. Prescription dose is 78 Gy. Note that this plan has nearly 100% of target volume (PTV) receiving prescribed dose, yet there is steep fall-off in target volume coverage beyond 78 to 80 Gy. This is typical for conventionally fractionated plans to avoid excessive dose within the prostate and immediate adjacent tissues. In contrast, stereotactic body radiation plans (see the Stereotactic Body Radiotherapy section in text) often have

portions of target volume intentionally receiving a higher-than-prescribed dose, with the rationale of increasing the dose to the intraprostatic tumor.

One of the goals of conformal prostate radiation is to lower the dose to the surrounding normal tissues, such as the rectum and bladder, while simultaneously increasing the dose delivered to the prostate itself (Burman et al., 1991; Niemierko et al., 1992). The use of CT data allows more accurate placement of the radiation fields; this was first demonstrated by Pilepich et al. (1982), who found a 53% error rate in field placement and portal size in patients simulated without CT data. In theory, better pretreatment visualization and localization of the prostate eliminate the need to enlarge the radiation portal to account for anatomic and geometric uncertainties. It logically follows that smaller radiation portals allow less irradiation of nontarget structures such as the bladder or rectum, thereby reducing treatment-related morbidity.

Intensity-Modulated Radiation Therapy

The ability to accurately calculate radiation doses to the prostate and surrounding organs facilitated further technologic developments that allowed delivery of higher radiation doses to the prostate while simultaneously lowering doses to surrounding organs. Another major advance in the delivery of radiation is IMRT. IMRT employs a similar process to 3D-CRT, but rather than the static, fixed-shape beams utilized in 3D-CRT, IMRT employs more complex, dynamic beam shapes wherein the intensity of radiation is varied across the beam (as opposed to uniform intensity across the beam). This allows for finer control of spatial variations in dose and can produce steeper dose gradients with improved sparing of normal tissues, particularly when tumors or tissues have complex, convex, or concave shapes. IMRT employs a complex treatment-planning approach referred to as *inverse treatment planning,* wherein users manipulate computer algorithms to calculate doses to achieve specified goals regarding areas where radiation dose is to be minimized (i.e., organs) and areas that are to receive high-dose treatment (i.e., prostate). This computer-optimized inverse planning requires use of advanced software, specialized personnel, and hardware adaptations to linear accelerators (Burman et al., 1997). With this technology, plans can be generated in which the majority of the adjacent bladder and rectum receive less than one-half of the dose given to the prostate. An example of an intensity-modulated plan is shown in Fig. 157.2, demonstrating a distribution of radiation that follows the contours of the prostate while sparing much of the rectum and bladder.

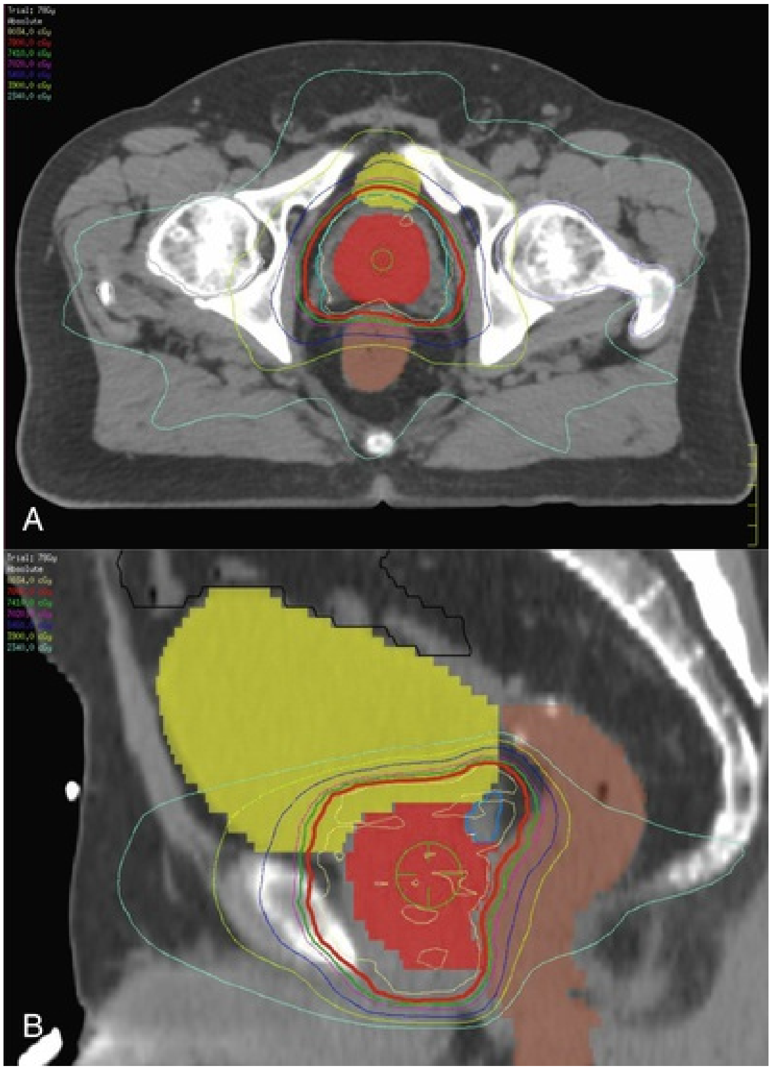

FIG. 157.2 Axial (A) and sagittal (B) views of an intensity-modulated radiation treatment plan (IMRT) showing prostate *(solid red),* bladder (base, *solid yellow*), and rectum *(solid brown).* Dose lines (isodoses) are shown in *thin colored lines* (key in *upper left* of image). Prescription dose isodose line (78 Gy, *thick red*) includes a margin around the prostate, with less margin posteriorly to minimize rectal dose. Note skin sparing, and concavity of posterior dose lines achieved by IMRT.

In multiple treatment-planning studies, IMRT has consistently demonstrated lowering of radiation doses to the rectum, bladder, femoral heads, and small bowel compared with 3D-CRT (Table 157.1). In 2000, almost every patient with prostate cancer in the United States treated with RT received conformal radiation; by 2009, almost 100% of prostate radiation was given using IMRT

(Sheets et al., 2012). The minor potential disadvantages to IMRT include increased treatment time and increased total monitor units ("beam on") required; however the advantages are considered to far outweigh these disadvantages. One solution to the increased treatment time is use of volumetric modulated arc therapy (VMAT), an innovative form of IMRT optimization in which radiation doses are efficiently delivered in a single 360-degree gantry rotation arc (Palma et al., 2008). In a comparison of intrafractional motion during VMAT treatment versus IMRT treatment, the average VMAT fraction was significantly shorter at 2 minutes and 43 seconds compared with the IMRT fraction at 6 minutes and 13 seconds (Ballhausen et al., 2018).

V*x* represents the percentage of an organ receiving *x* Gy of radiation dose.

Image-Guided Radiation Therapy and Treatment Margins

In addition to improvements in shaping the treatment to the target, methods for aligning the beams to the prostate with greater spatial accuracy have also been developed. A more recent and clinically important development has been the addition of **image guidance** to prostate cancer RT. Image guidance was developed based on a realization that (1) the daily location of the prostate within the pelvis throughout the course of RT is not identical (interfraction motion) (Beard et al., 1996; Ten Haken et al., 1991) and (2) the prostate is mobile, even during a single session of RT (intrafraction motion) (Huang et al., 2002).

Treatment margins or target volume expansions are utilized in the treatment-planning process to consider the potential for several uncertainties and variables in targeting, including daily patient alignment, patient or prostate motion, microscopic extension of disease, and uncertainty in defining target/tissue boundaries on simulation imaging and contouring. The International Commission on Radiation Units and Measurements has defined three major concepts for target volumes in *Radiation Oncology:* **gross tumor volume (GTV), clinical target volume (CTV), and planning target volume (PTV).** During the treatment-planning process, these structures are defined on images by the radiation oncologist and utilized for planning treatment. The definitions of these volumes can be summarized as follows:

- GTV: the grossly palpable or visible location of malignant growth
- CTV: tissue volume that contains the GTV plus any subclinical microscopic disease
- PTV: takes into consideration the net effect of all possible geometric variations and inaccuracies to ensure that the prescribed dose is actually absorbed in the CTV. Used to compensate for effects of organ and patient movement, and inaccuracies in beam and patient setup.

In the case of prostate cancer, the entire prostate (plus any visible extraprostatic extension of disease) is contoured as the GTV. The CTV typically includes GTV plus a portion of adjacent seminal vesicle, depending on the clinical stage, Gleason score, and other prognostic factors associated with seminal vesicle invasion (Kestin et al., 2002b), and may also include pelvic nodes (typically including external iliac, internal iliac, obturator, and presacral) for patients deemed at risk for nodal involvement (Harris et al., 2015). The prophylactic inclusion of clinically uninvolved lymph nodes in the target volume is controversial, however, and is discussed in the Role of Prophylactic Pelvic Node Treatment section later in this chapter.

The use of treatment margins allows for greater confidence that the target volume will reliably include the tumor, but comes with a tradeoff for increased toxicity because greater volumes of normal tissue are added to the treated volume. In the past, uncertainty in patient and prostate positioning reproducibility forced radiation oncologists to utilize larger margins and accept the risk for increased morbidity. With image guidance, the treatment margins are reduced significantly because the location of the prostate can be verified daily before delivering radiation.

Online **image-guided radiation therapy (IGRT)** refers to daily treatment imaging to localize the prostate and make positional adjustments to the patient immediately before each treatment (Boda-Heggemann et al., 2011). The use of implanted fiducial markers, cone-beam CT, and three-dimensional ultrasonography are all prostate-targeting techniques that can improve treatment accuracy. Because determining the exact alignment of the prostate on CT images can be subject to interuser variability, intraprostatic fiducial markers (typically 2 to 4 gold or gold-containing seeds or coils ~5 × 1 mm in size placed under ultrasound guidance) are frequently utilized to improve the accuracy and reproducibility of prostate localization. These allow for ready visualization and alignment of the patient on the linear accelerator by serving as a simple surrogate for prostate position. With the use of soft-tissue images for daily alignment, treatment margins of 3 to 7 mm are generally employed and account for potential misalignments resulting from interuser variability of image interpretation (Kupelian et al., 2008).

There are several “in-room” CT solutions used for IGRT that allow for direct imaging of the pelvis and prostate within the same treatment room as the linear accelerator, including helical kilovoltage on-rail CT (the patient can be moved from the scanner to the linear accelerator while remaining on the treatment table), kilovoltage cone-beam CT (the linear accelerator also has an integrated kilovoltage source along with cone-beam imaging flat panels), or helical megavoltage CT scanners (the imaging energy source is the megavoltage beam itself). These daily in-room CT techologies allow use of bony anatomy, implanted fiducials, and soft-tissue images to align the prostate (Fig. 157.3A–C). In addition, soft-tissue images can also identify daily variations in filling of other structures such as the rectum and bladder. The use of IGRT has been shown to be associated with both improvements in biochemical tumor control and lower rates of late urinary toxicity (Zelefsky et al., 2012). IGRT can also reduce the amount of rectum receiving the high-dose radiation volume, leading to lower rates of radiation-induced proctitis (Jani et al., 2003). The disadvantage to the cone-beam CT technique is the additional dose received by the patient (van Zijtveld et al., 2010) at around 2 to 3 centiGray (cGy) per cone-beam CT acquisition (Alaei and Spezi, 2015). Although transabdominal ultrasound systems are another method for visualizing the prostate and bladder, significant interuser variability exists (Langen et al., 2003; Pinkawa et al., 2008). This technique has fallen out of favor because of concerns regarding displacement of the prostate during imaging that does not persist at the time of treatment and results in systematic positioning error (Lin et al., 2008).

FIG. 157.3 Modern linear accelerator with imaging capability. (A) The radiation treatment beam is shaped by a collimator contained within the

treatment head *(top).* The panel *(right)* contains a kilovoltage unit for generating cone-beam computed tomography (CT) images. Two moveable imaging panels are present. The imager panel *(left)* is for capturing kilovoltage two-dimensional or cone-beam images (obtained by rotating the entire unit around the patient), whereas the unit on the bottom (opposite from the treatment head) allows for megavoltage imaging confirmation of beam shape in addition to three-dimensional CT reconstruction. The patient lies on the carbon-fiber treatment couch *(black),* which can be moved in three dimensions *(x, y, z),* and rotated in all directions (pitch, yaw, roll). (B) Example of cone-beam alignment images. Planning (simulation) images *(light gray panels)* are overlain with a cone-beam image acquired before each treatment *(dark gray panels).* Internal anatomy is aligned between the two image sets, and the treatment couch is moved accordingly (i.e., table correction). (C) Example of a fiducial marker-based alignment. Fiducial (typically gold) markers within the prostate allow for either orthogonal two-dimensional *(shown)* or three-dimensional on-board CT imaging alignment of prostate before each daily treatment session. (A, Used with permission from Elekta Inc.)

Neither approach, however, addresses the issue of **intrafraction motion.** One solution to the intrafraction motion problem is prostate immobilization, which can be achieved using an intrarectal balloon introduced into the rectum and inflated before daily RT. Inflation of the balloon pins the prostate against the pubic bone and prevents rectal motion. Because the immobilized prostate does not move during treatment, relatively tighter posterior margins can be used (Fig. 157.4). Also, although the anterior rectal wall may be pushed closer to the prostate, the lateral and posterior walls are pushed further away, thereby reducing the overall dose to the rectum (Sanghani et al., 2004). Another option for intrafraction tracking is with implanted radiofrequency transponders that generate electromagnetic signals that allow three-dimensional localization during treatment (Kupelian et al., 2007). Traditionally these transponders required percutaneous implantation with a 14G needle. However, newer versions use a smaller 17G beacon. A potential disadvantage of this system is the significant artifact caused by the transponders on any magnetic resonance imaging (MRI) scans the patient may require in the future. Interfraction and intrafraction motion of the prostate can also be reduced with daily pretreatment bladder filling (having patients drink 16 to 30 ounces of water before treatment (Mullaney et al., 2014)) and with rectal emptying to minimize peristaltic and gas-related motion (Stasi et al., 2006).

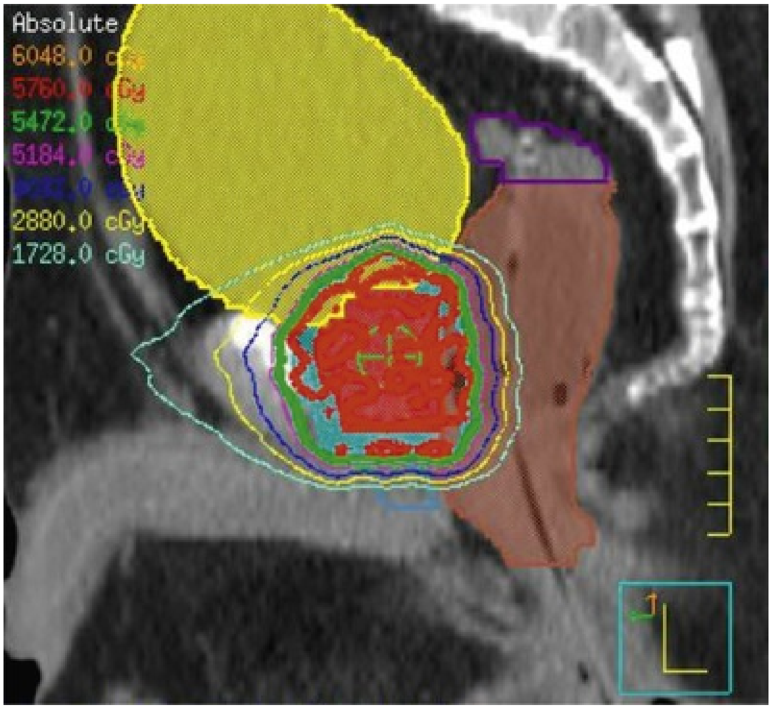

FIG. 157.4 Sagittal view of a treatment plan utilizing a rectal balloon.

The ability to account and correct for uncertainties in the location of the prostate on a daily basis allows for accurate delivery of radiation to the prostate while further lowering incidental doses received by surrounding organs. This becomes increasingly important when using hypofractionated or stereotactic body radiation therapy (SBRT) (discussed later), which is dependent on the ability to precisely direct treatment to the intended target. Image guidance is now a recommended standard of care for prostate cancer RT (National Comprehensive Cancer Network [NCCN], 2016).

Multiparametric Magnetic Resonance Imaging in Radiation Treatment Planning

Multiparametric MRI combines morphologic and functional MRI sequences including T2-weighted, diffusion-weighted, dynamic contrast-enhanced (DCE) and magnetic resonance spectroscopic imaging, and its use in conjunction with an endorectal coil and a higher-strength (3-tesla [T]) magnet may have significant prognostic utility. Researchers from the National Cancer Institute (NCI) found a strong correlation between apparent diffusion coefficients (ADC) derived from diffusion-weighted imaging and both Gleason score (P = .003) and clinical risk group (P < .0001) (Turkbey et al., 2011). In addition, in a study of

100 favorable-risk men who received radical prostatectomy (RP), 3T multiparametric endorectal MRI was 75% and 95% accurate at predicting pathologic extracapsular extension and seminal vesicle invasion, respectively (Hegde et al., 2013). Therefore MRI may be a useful tool in further stratifying risk in patients who are borderline between two treatment options, such as intermediate-risk patients considering monotherapy with radiation alone versus combined modality therapy with radiation and short-course androgen deprivation therapy (ADT). Multi-parametric MRI can also be incorporated with MRI-TRUS fusion for targeted biopsies, which increases the diagnosis of high-grade prostate cancer with fewer biopsy cores needed (Rastinehad et al., 2014; Wysock et al., 2014). (see Chapter 152 for further discussion regarding diagnostic MRI techniques and prostate cancer staging).

At some centers, MRI is integrated into the radiation treatment-planning process. Because CT is still required to accurately calculate dose (based on tissue density), MRI images are coregistered and fused with CT to allow simultaneous visualization of both. Studies have demonstrated that prostate volumes delineated on MRI are 10% smaller than those delineated on CT, with improved identification of the prostate particularly at the apex and the base (Ménard et al., 2018). MRI also can be especially useful when CT image quality is compromised, such as artifact from prosthetic hip implants, or when PTV margins are small. MRI can also improve dosimetric accuracy in post-planning low-dose-rate (LDR) brachytherapy to help delineate the prostate.

MRI T2 sequences in addition to an MRI angiogram have been used to delineate and avoid erectile vasculature in a vessel-sparing RT approach (Lee et al., 2016b). In a prospective single-arm study by Spratt et al. (2017b), of 135 men treated with vessel-sparing RT utilizing planning MRI and MRI-angiogram, 88% of men were sexually active at 5-year follow-up, which is significantly higher than previous studies utilizing radiation or nerve-sparing prostatectomy. However, further research is needed to determine whether this approach truly reduces the risk for post-treatment erectile dysfunction (ED), particularly given the uncertainty regarding which normal tissue is sensitive to and responsible for radiation-induced ED.

Transrectal Ultrasound-Guided Brachytherapy

Brachytherapy (from the Greek word *brakhus*, meaning “short”) is the placement of radioactive sources into or near tumors for therapeutic purposes.

As noted earlier, Pasteau (1913) first described the temporary placement of radium-containing needles into the prostate through the urethra. During the 1920s, Hugh Hampton Young (1922) at Johns Hopkins University performed prostate brachytherapy using intracavitary radium sources in the bladder, rectum, and urethra with the overlapping dose “cross-firing” into the prostate. This technique was refined at Memorial Hospital in New York by Benjamin Stockwell Barrington, who pioneered implanting needles containing radioactive radon gas into the prostate by a transperineal approach. Whitmore et al. (1972) at Memorial Sloan Kettering Cancer Center in New York performed ^{125}I implantation in patients in conjunction with lymph node dissection. The prostate would be exposed for implantation via a retropubic surgical incision, with the prostate measured using calipers to determine the number of seeds required. Needles were inserted in an anterior-to-posterior direction, with seed placement also palpably guided by having a gloved finger in the rectum to avoid needle penetration through the anterior rectal wall. However, this “freehand” technique resulted in suboptimal distribution of seeds because of multiple factors, including lack of visualization, difficulty achieving regular and parallel needle spacing, bleeding from puncture of the periprostatic venous plexus, and inadvertent passage of needles through the rectum or bladder, with associated infection risk (Kumar and Bartone, 1981; Zelefsky and Whitmore, 1997).

Holm et al. developed the basis for the modern method of brachytherapy using transrectal ultrasound (TRUS), which allowed the insertion of radioactive sources under live image guidance (Iversen et al., 1989). For this procedure, the patient is placed in a high lithotomy position to maximize the transperineal exposure of the prostate. The transrectal ultrasound probe is inserted and held within a mount (also referred to as a *stepper*) that itself is held within a pedestal that is either mounted to the procedure table or the floor. The stepper allows for precise rotation of the probe along its axis, and/or cranial-caudal movement of the probe in measured increments. This setup provides relatively fixed positioning of the prostate throughout the procedure, and subsequently more accurate and reproducible imaging. A template with a predrilled pattern of parallel holes is held against the perineum by the stepper. The template pattern is also superimposed over the ultrasound image by computer software in the ultrasound base unit, allowing for correlation of the template grid pattern to specific positions within the prostate. Needles of 17- or 18-G are inserted through the template into the prostate. The position of the needle tip can be confirmed by transverse or parasagittal imaging. Sealed metallic seeds containing the radioactive isotope are deployed as the needle is withdrawn (Fig. 157.5).

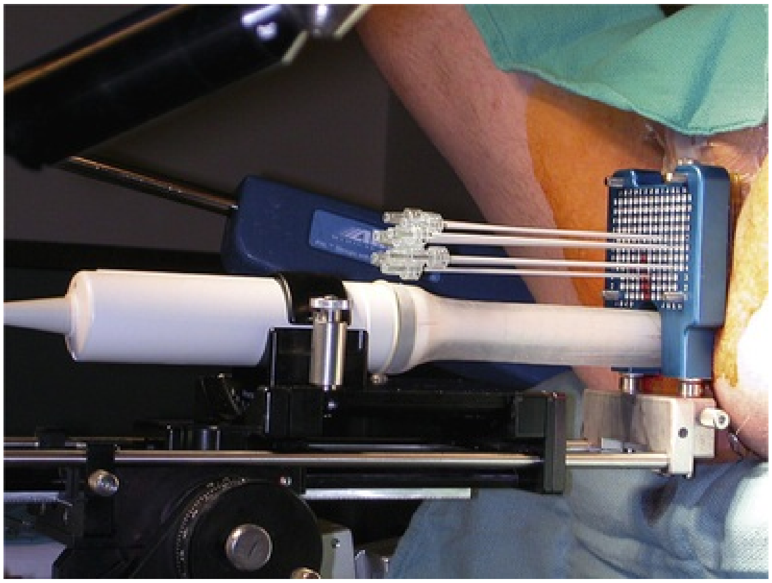

FIG. 157.5 Lateral view of a transrectal ultrasound probe (TRUS) held within a stepper cradle *(black).* The patient is in the high lithotomy position. The template grid is positioned against the perineum, and either needles (low-dose-rate) or catheters (high-dose-rate) are placed through the grid into the prostate. (From Morton GC. The emerging role of high-dose-rate brachytherapy for prostate cancer. *Clin Oncol* 17[4]:219–227, 2005.)

With this approach, the needles used to insert the radioactive seeds can be visualized, with significant improvement in the accuracy of seed placement. This was a significant step forward over the prior imprecise freehand technique, in which access to the apex was limited and achievement of source distribution and dose coverage technically challenging.

The use of the TRUS guidance technique intraoperatively provided the potential for delivering more uniform coverage and adequate doses of radiation within the prostate gland while limiting dose to the prostatic urethra and the anterior rectal wall.

Other noteworthy methods that have been employed for seed implantation include a trans-sacral, CT-guided approach (Koutrouvelis, 1998) and a method using intraoperative MRI guidance (D'Amico et al., 1998; Susil et al., 2004), but neither method appears to be in utilization today.

Key Points: Historical Perspectives and Technological Advances

- Linear accelerators produce photons (x-rays); increasing photon energy results in more skin sparing and deeper penetration of dose into tissues.
- Dose-volume histograms (DVHs) are used to graphically summarize the amount of radiation received by the different regions of interest (tumor and normal tissues/organs).
- Treatment margins are utilized to account for potential subclinical extension of disease, setup variability, and potential interfraction and intrafraction motion. Advances in radiation treatment planning and imaging have resulted in the ability to use subcentimeter treatment margins while maintaining targeting accuracy, thereby reducing toxicity.
- Intensity-modulated radiation therapy (IMRT) is most commonly utilized for definitive prostate cancer treatment. IMRT allows for dose distributions that have higher conformality to the target via improved shaping of dose within and around tissues, thereby maximizing the dose of radiation that can be safely delivered.
- Prostate brachytherapy is performed under transrectal ultrasound guidance; seeds are placed in a peripherally loaded pattern to minimize the dose to the urethra.

External Beam Radiation Treatment (Also See Outcomes for External Beam Radiation)

Fractionation in Radiation Therapy

Fractionated treatment has been used since the early days of RT, when it was found that tumor control could be achieved with less normal tissue injury when the radiation dose was split into many small fractions (Coutard, 1932). For decades, EBRT has been routinely delivered in a fractionated manner using daily doses of 1.8 to 2.0 Gray (Gy; the SI unit for radiation, defined as the absorption of 1 Joule per kilogram of matter). This fraction size was based on early clinical experience and animal data, and supported by experimentally derived mathematical models of normal tissue and tumor response to fraction size. The most widely used of these models is the **linear-quadratic formula**, which predicts responses to different fraction sizes based on the **alpha/beta ratio** of any given tissue (Fowler, 1989).

One of the main motivations for delivering a treatment at low-dose rate or with many fractions is that late-responding normal tissues are generally more sensitive than early-responding tissues (i.e., tumor) to increases in fraction size. In particular, what is generally considered “late” radiation toxicity (occurring ≥90 days after completion of treatment) was found to be reduced with the use of fractionation. Therefore increasing the number of fractions generally spares late-responding tissues more than the tumor. This can be quantified in terms of the alpha/beta ratio:

- Small alpha/beta ratio (2 to 4 Gy), typical of late sequelae, means high sensitivity to fractionation changes.
- Large alpha/beta ratio (>8 Gy), typical of tumor control, means low sensitivity to fractionation changes.

Radiobiologic Basis for Hypofractionation

It is generally assumed that the mechanistic basis for the different fractionation responses of tumors and late-responding normal tissues relates to the larger proportion of cycling cells in tumors. But prostate tumors contain unusually small fractions of cycling cells (Haustermans et al., 1997). Brenner and Hall (1999) and Duchesne and Peters (1999) have reasoned that prostate tumors might not respond to changes in fractionation in the same way as other cancers; both papers hypothesize that prostate tumors might respond to changes in fractionation or dose rate more like a late-responding normal tissue. In mathematical terms, the suggestion is that the alpha/beta ratio for prostate cancer might be low, comparable to that for late-responding tissues or even lower. Previous estimates of alpha/beta ratios of normal tissue and tumor tissue have generally been 3 and 10, respectively, but recent evidence has estimated the alpha/beta ratio of prostate cancer to be as low as 1.5. If these hypotheses are true, then the optimal therapeutic ratio for prostate cancer would be achieved using daily doses higher than 2 Gy (Valdagni et al., 2005). By exploiting the low alpha/beta of prostate cancer and using higher than standard doses per fraction, one could potentially lower total dose, thus lessening the risk for normal organ injury, while maintaining similar or even improving prostate cancer control (Withers, 1985).

The support for this hypothesis is based on clinical studies in which the treatment dose was varied. The first report suggesting this relatively unique sensitivity to high dose per fraction was by Brenner and Hall (1999), who used the 3-year freedom from biochemical failure rates of 134 patients receiving permanent brachytherapy and 233 patients receiving EBRT to calculate an alpha/beta ratio of 1.5 Gy. This radiobiologic value is used to calculate the radiosensitivity of a tissue. For comparison, the alpha/beta ratio of head and neck cancers is thought to be between 13 and 16 Gy, whereas late-responding skin fibrosis has an alpha/beta ratio of 1.7 Gy (Zeman, 2006). Although intriguing, this study brought criticism for its comparison of data from several radiation modalities, which vary not only in dose per fraction but also in spatial distribution qualities of the radiation delivered. However, more recent studies evaluating large cohorts treated with EBRT continue to support the premise of prostate cancer sensitivity to high dose per fraction. Dasu and Toma-Dasu (2012) evaluated the 5-year biochemical control from 11,330 patients treated with EBRT, accounting for overall treatment time, and found that, depending on risk category, the alpha/beta ratio varied from 1.0 to 1.7 Gy. A second study found an alpha/beta ratio of 1.4 Gy using 5969 patients receiving EBRT (Miralbell et al., 2012). Table 157.2 illustrates how hypofractionation may provide a greater effective dose to the prostate without greater effect on normal tissues, assuming the alpha/beta ratio for prostate is lower than for normal tissues.

TABLE 157.2

Example of Alpha/Beta Ratio and Effect of Hypofractionation for Prostate, Bladder, and Rectum

TISSUE OF INTEREST	ALPHA/BETA RATIO (Gy)	BIOLOGICALLY EQUIVALENT DOSE (IN 2-Gy FRACTIONS) of 37.5 Gy IN 5 FRACTIONS
Prostate cancer	1.5	96 Gy
Rectum/bladder	3	79 Gy

The biologically equivalent dose in 2-Gy fractions is shown using the alpha/beta ratio for prostate and for late effects on rectum and bladder. Intensity-modulated radiation therapy has shown an acceptable safety profile up to ~78 to 81 Gy in 2-Gy fractions (Alicikus et al., 2011). If alpha/beta of prostate is 1.5 Gy, then a 5-fraction regimen totaling 37.5 Gy has relatively greater effect on prostate cancer similar to 96 Gy in standard fractionation, while maintaining similar effect on the rectum and bladder.

Stereotactic Body Radiation Therapy

Varying regimens of hypofractionation have been employed in clinical trials, and terminology has been coined to describe the degree of hypofractionation. Moderate **hypofractionation** is generally considered to be that which uses doses of 2.4 to 4 Gy per day, whereas ultra (or extreme) hypofractionation uses doses of 6 to 10 Gy per fraction (Cabrera and Lee, 2013). When ultrahypofractionation is given, treatment is often delivered fewer than 5 days per week (i.e., every other day) to allow normal tissue recovery between treatments. An entire treatment course of ultrahypofractionation is typically completed within 2 weeks.

Although the potentially low alpha/beta ratio of prostate cancer supports treatment with a few large fractions, care still must be taken to protect the nearby bladder and rectum, which also are relatively sensitive to high dose per fraction. The advent of ultrahypofractionation was concurrent with technology that allowed for higher accuracy and conformality. SBRT is defined as RT that delivers a relatively high dose per fraction, using tighter treatment margins than are typically employed for conventionally fractionated treatment (often 3 to 5 mm, vs. 10 to 5 mm for conventional fractionation). More stringent methods for intrafraction monitoring of prostate position are employed, either via onboard

CT captured at times during beam delivery, or intermittent tracking of implanted fiducial markers using kV imagers. Dose within the plan may also be more heterogeneous, with the goal of delivering higher doses to portions of the prostate (Benedict et al., 2010). SBRT can be performed in a traditional **linear accelerator,** but is also commonly performed using a compact X-band linear accelerator mounted on a robotic arm (CyberKnife, Accuray, Sunnyvale, CA). The robotic arm allows 6 degrees of freedom in conjunction with two cross-firing kilovoltage imagers to allow for intrafractional tracking of target motion, which requires implanted fiducial markers within the prostate (Kilby et al., 2010). One potential disadvantage of the robotic system is the longer treatment delivery time, typically 30 to 40 minutes (compared with 15 to 20 minutes on a conventional linear accelerator).

A recent analysis of the U.S. National Cancer Database from 2004 to 2012 showed that the relative utilization of SBRT increased from 0.1% in 2004 to 4.0% in 2012. Initially SBRT was more commonly used in academic programs, though as time progressed there was a shift to favor an increased absolute number of men treated in the community setting. Delivery of five separate treatments was the most commonly utilized fractionation pattern, with 91% receiving this number of treatments. The most common dosing pattern was 725 cGy × 5 fractions (49.6%) followed by 700 cGy × 5 fractions (21.3%) (Weiner et al., 2017).

Heavy Particle Beams/Proton Therapy

A common application of particle therapy is with the **electron** beam, which can be generated by all modern linear accelerators. As compared with photons, electrons have much shallower depth penetration, and are therefore used for skin or other superficially located tumors. Other particles such as protons, neutrons, helium ions, heavy ions (neon, argon, carbon), and negative ions are available as well. These **heavy particle beams** are much more difficult to produce and to control, but have certain physical advantages over photon and electron beams that have led to great interest in exploiting these advantages. Because they have greater **linear energy transfer** (amount of energy deposited by radiation per unit length of travel) when compared with photons, they are more densely destructive to cellular DNA, and the damage they create is less easily repaired by tumor cells. This results in their having a slightly higher **relative biological effectiveness,** or clinical effect per given dose in tissue compared with photons.

In addition, they travel differently in tissue and exhibit a **Bragg peak**, which refers to a sharp increase and subsequent cutoff in dose at the end of the particle's range. Thus, in theory it could be easier to spare the normal tissues surrounding the cancerous target. However, the sharp increase followed by decrease of dose in the Bragg peak is impractical for treating most tumors because the thickness of the target is usually greater than the Bragg peak. Therefore, in practice the proton beams are modified such that the dose is more spread out over a distance, referred to as a **spread-out Bragg peak** (Fig. 157.6) (Bortfeld and Schlegel, 1996).

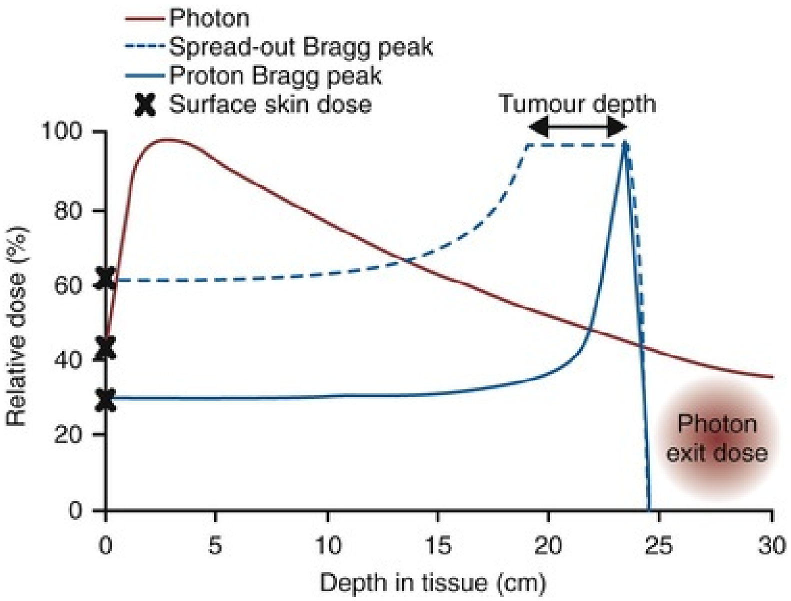

FIG. 157.6 Dose-depth characteristics of protons and photons. Protons have improved skin- and tissue-sparing properties, as a result of the Bragg peak. However, because of the narrow effective range of the Bragg peak differing from the thickness of most tumors, clinical treatments modulate the protons to create a spread-out Bragg peak (SOBP). (From Leeman JE, Romesser PB, Zhou Y, et al. Proton therapy for head and neck cancer: expanding the therapeutic window. *Lancet Oncol* 18[5]:e254–e265, 2017.)

Proton and heavy ion dose calculations are also susceptible to uncertainties that could lead to underdosing of the target or overdosing of normal structures. Variations in patient positioning, tissue/organ motion, and tissue heterogeneity have potentially larger effects on proton dose calculation and distributions as compared with photons because of greater complexities of calculating beam range, i.e., **range uncertainty** (McGowan et al., 2013). Also, challenges in accounting for variations in relative biologic effectiveness, particularly within the edges of the spread-out-Bragg peak, can create uncertainties in predicting the clinical effects of a treatment plan (Britten et al., 2013).

The most commonly used particles are **neutrons** and protons. The Radiation Therapy Oncology Group (RTOG) sponsored a phase III trial in 1977 in which 91 patients with prostate cancer were randomly assigned to receive treatment with neutrons or conventional radiation (photons) (Lawton et al., 1991). At 10 years, survival was better in the neutron arm (46%) than in the photon arm (26%). However, patient characteristics were not equally balanced between the two arms. Poor prognosticators such as stage D1 disease were more common in the photon arm, and the observed survival difference between the two groups may have been because of this aspect more than any therapeutic benefit of neutrons per se. However, the data were compelling enough to lead the NCI to fund the construction of several state-of-the-art neutron beam facilities, and trials were undertaken to study the efficacy and morbidity of neutron treatment. In the mid-1980s, a second prospective randomized trial was undertaken by the RTOG. A group of 178 patients with prostate cancer were randomly assigned to receive either neutron beam or conventional photon treatment. The local control rate was higher for the patients who received neutron therapy than for those who received photons (89% vs. 68%), as was the 5-year rate of freedom from PSA failure (83% vs. 55%). However, survival rates were no different in the two arms. Morbidity was higher in patients who received neutron beam treatment and was described as severe in 11%, compared with 3% for those who underwent photon irradiation.

In general, acceptance of neutron beam therapy by radiation oncologists has been limited because of the perception that complication rates are high without much gain in tumor control, and because of the limited availability and expense associated with neutron production. Over time, a form of conformal neutron beam therapy was developed and became possible in several centers (Forman et al., 1995). At Wayne State University, 300 patients were entered into a phase III trial and randomly assigned to conformal neutron therapy followed by standard CRT or CRT followed by a neutron therapy boost. A statistically significant difference in 5-year disease-free survival was seen for patients treated with neutrons first (93% compared with 73%, $P = .008$) (Forman et al., 2002). Treatment-related morbidity was the same for both groups in this study. A larger retrospective review from the same group of neutron therapy and photon CRT revealed a statistically significant improvement in 5-year relapse-free survival for the group that received neutrons as any component of their therapy. The effect was most pronounced for high-risk patients who had a 35% 5-year relapse-free survival rate versus 7% in the photon-only group ($P = .0004$). Although these data are provocative, one criticism is that the relapse-free survival in the photon-only group from Wayne State University was much lower than that of other series reporting on the same population of patients.

Despite the data from Wayne State University, most radiation oncologists believe that neutron beam therapy causes greater normal tissue damage than photon beam therapy. Investigators from the Catholic University of Louvain, Belgium, used a mailed questionnaire to assess quality-of-life changes in 262 patients who received mixed neutron-photon irradiation. Of the 230 patients who replied, 22% had four or more bowel movements per day. Retaining stool was a problem in 26% of the patients, and only 38% reported full bowel continence. The patients in this trial received neutron beam therapy using equipment that was not conformal. These data were sufficiently concerning to close their program and they demonstrate the importance of up-to-date equipment and technology for the delivery of neutron beam therapy. Today, few patients with prostate cancer in the United States are treated with neutron RT.

Proton beams are also used to treat cancer. Although proton radiation is not a new treatment for prostate cancer, there has been significant recent interest in its use for prostate cancer (MacReady, 2012; Zietman, 2007). Protons are charged particles generated by a linear accelerator, cyclotron, or synchrotron. In the 1980s, a prospective randomized trial was undertaken in men with locally advanced prostate cancer (Shipley et al., 1995). Patients treated with proton beams had a 95% incidence of clinical local control at 5 years, compared with a 64% incidence for those treated with photons. Although no grade 3 to 5 toxicities were reported in either arm of this trial, grade 1 and 2 rectal bleeding rates were higher in the proton group (32% vs. 12%, $P = .002$), as were urethral strictures (19% vs. 8%, $P = .07$). When the group with rectal bleeding was carefully analyzed, a relationship between the volume of rectum treated and the dose of protons given was established and guidelines were developed for future trials (Hartford and Zietman, 1999).

Another early study utilizing protons was a dose escalation study in which men with low- and intermediate-risk prostate cancer all received conformal photon radiation to 50.4 Gy followed by a proton boost to either 70.2 Gy or 79.2 Gy (Zietman et al., 2010). Ten-year biochemical failure rates were 32.4% in the conventional dose group compared with 16.7% in the high-dose group. There was no difference in overall survival or grade ≥3 urinary or bowel toxicity between the treatment arms. Given that both arms were treated with protons, however, this study did not allow for a true comparison of proton versus photon effectiveness.

Studies comparing proton therapy to modern IMRT for prostate cancer are mostly limited to treatment-planning studies, which have shown that proton radiation can reduce the volumes of nearby organs that receive low to medium—but not high—doses of radiation (Table 157.3). For example, in a study by Trofimov et al. (2007), proton plans to 79.2 cobalt Gray-equivalent (CGE) were created for 10 patients using parallel opposed lateral fields, a commonly used technique for prostate cancer. They noted that proton therapy allowed a smaller proportion of the rectum to receive low doses of radiation (<30 CGE) compared with IMRT. However, proton plans did not reduce the volume of rectum receiving high doses of radiation. Another study by Vargas et al. (2008), using two proton beams but with angles optimized to minimize rectal and bladder dose, similarly demonstrated a reduction in rectal volume receiving low-to-moderate radiation doses, but minimal benefit in the volume of rectum receiving high-dose radiation. Studies that found improvements in rectal sparing with proton therapy tended to find improvements in bladder sparing as well. Again, the most significant benefit was in reducing the volume of bladder receiving low-to-medium doses, but not high doses (Chera et al., 2009; Mock et al., 2005; Trofimov et al., 2007; Vargas et al., 2008). The study by Trofimov et al. (2007) reported better bladder sparing by proton therapy at doses lower than 30 CGE compared with IMRT, but protons actually resulted in a higher volume of the bladder receiving a high dose of 70 CGE (17% for proton vs. 11% for IMRT). Similarly, Vargas et al. (2008) found bladder sparing at doses from 10 to 35 Gy, but not at doses above 60 Gy.

TABLE 157.3

Treatment Planning Studies Comparing Intensity-Modulated Radiation Therapy vs. Conformal Proton Therapy

REFERENCE	TREATMENT TARGET	DOSIMETRIC MEASURE	RECTUM IMRT/PROTON	BLADDER IMRT/PROTON
Chera et al., 2009	Prostate + SV + LN	Max dose (Gy)		
		Mean dose (Gy)	40.9/16.6	42.1/21.2
		V10 (%)	92.7/35.1[a]	100/46.2[a]
		V50 (%)	27.3/15.1	25.6/18.2

		V70 (%)	11.5/7.9	9.7/9.8
Vargas et al., 2008	Prostate ± SV	Mean dose (Gy)	34.8/14.2[a]	28.4/18.4[a]
		V10 (%)	72.1/29.8[a]	60.0/36.4[a]
		V30 (%)	55.4/20.7[a]	42.8/27.7[a]
		V50 (%)	31.3/14.6[a]	
		V70 (%)	14.0/7.9[a]	
		V78 (%)	5.0/2.9[a]	
Trofimov et al., 2007	Prostate + SV	Mean dose (Gy)	39.4/29.2[a]	29.9/24.1[a]
		V30 (%)	65.3/43.8[a]	44.5/32.8[a]
		V50 (%)	34.4/28.2[a]	23.7/25.4
		V70 (%)	14.5/14.0	11.4/17.3[a]
		V75 (%)	9.7/10.3	

[a] Statistically significant difference.

IMRT, intensity-modulated radiation (photon) therapy; *LN,* lymph nodes; *SV,* seminal vesicles.

Unlike IMRT, which employs several beams or arcs, proton treatment for prostate cancer often involves only two beams, which are typically two opposed (opposing) lateral beams. This is done to keep the beams parallel to the prostate-rectum interface and thus minimize the risk for range uncertainty leading to underestimation of dose to the rectum. The opposed lateral beam arrangement used in proton therapy raises concern over the dose received by **femoral heads**, with associated risk for **avascular necrosis.** Several studies identified similar or worse femoral head dose distributions using protons compared with IMRT, especially when pelvic nodes are included in the treatment target as reported by Chera et al. (mean femoral dose 31 CGE for proton vs. 22 Gy for IMRT) (Chera et al., 2009; Mock et al., 2005; Trofimov et al., 2007). In a case-matched study of toxicity after either proton therapy or IMRT, Fang et al. (2015) found no significant difference in risk for grade ≥2 acute or late gastrointestinal (GI) or genitourinary (GU) toxicity. Whether the reduction in low-to-moderate doses of radiation to the rectum from proton therapy results in lower GI toxicity rates compared with IMRT is unknown; conversely, it is unknown if proton therapy causes higher rates of GU toxicity or pelvic fracture and avascular necrosis rates as a result of somewhat higher doses to the bladder and femoral heads. A matched-pair analysis of Harvard cyclotron patients versus SEER registry data also found no benefit from protons in reducing the incidence of secondary malignancies compared with photon therapy (Chung et al., 2013).

To date, no clinical trial has directly compared patient outcomes of proton therapy versus modern IMRT for prostate cancer. Available studies include single-arm (proton therapy) series mostly from a single institution or a few institutions (Bryant et al., 2016; Coen et al., 2011; Mendenhall et al., 2012; Slater et al., 2004). Among 1327 men treated with dose-escalated proton therapy, Bryant et al. (2016) reported that 5-year freedom from biochemical progression was 99%, 94%, and 74% in low-risk, intermediate-risk, and high-risk patients, respectively. Ho et al. (2018) also showed promising long-term patient-reported outcomes after proton therapy. Among 254 men treated with proton therapy with a median follow-up of 7.1 years, biochemical recurrence–free survival was 97.8%, with sexual potency reported of 72% at 1 year and 67% at 5 years compared with a baseline of 90%. The urinary irritative and bowel scores declined initially from baseline at year 1, but improved over the following 3 to 4 years to near baseline. These data suggest that proton therapy is safe and effective for prostate cancer treatment and likely results in cancer control and morbidity outcomes similar to those with IMRT. However, because proton-beam treatment units are extremely expensive to construct and operate, proton therapy represents an expensive treatment option for prostate cancer that currently has not demonstrated a clinical benefit over standard IMRT (Schroeck et al., 2017; Sheets et al., 2012). In light of this knowledge, insurer reimbursement for proton treatment has declined over the past few years, and has put financial pressure on some proton centers (Piana, 2015). An ongoing multi-institutional randomized clinical trial (PARTIQoL) is comparing proton therapy to IMRT in men with low- or intermediate-risk prostate cancer. The primary outcome measured is mean Expanded Prostate Cancer Index Composite (EPIC) bowel scores at 24 months after radiation. Results of this study may provide randomized evidence to help guide treatment decisions regarding proton therapy in the treatment of prostate cancer.

Key Points: External Beam Radiation Treatment

- Hypofractionated regimens may increase the therapeutic ratio of treatment if prostate cancer has a low alpha/beta ratio.
- Ultrahypofractionated RT employs fractions of 6 to 10 Gy, typically in 5 fractions or less.
- Protons have higher relative biologic effectiveness compared with photons, and doses must be considered accordingly.

- The Bragg peak allows for protons to achieve very low entrance and exit doses to nontarget tissues. A spread-out Bragg peak is often used clinically to allow adequate dosing of the entire tumor depth.
- No randomized clinical trial has directly compared patient outcomes of proton therapy versus IMRT for prostate cancer.

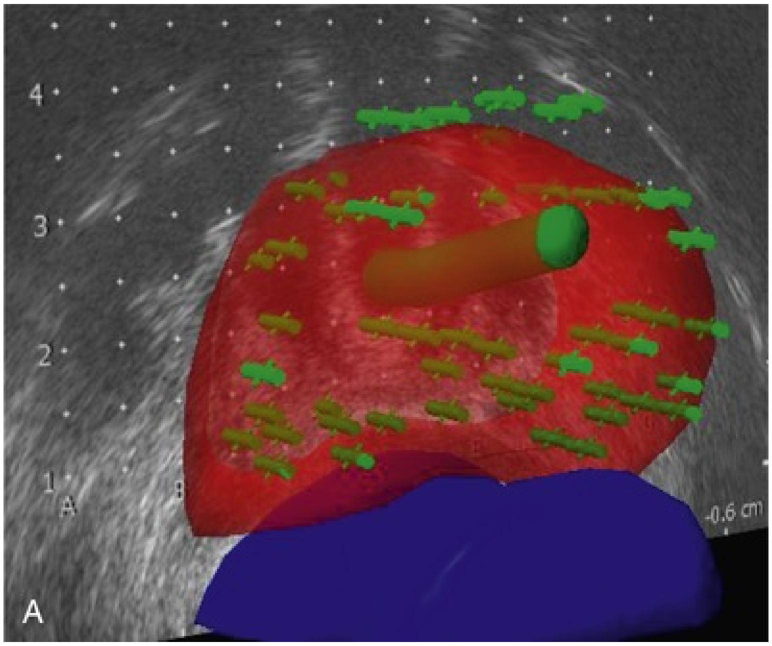
Brachytherapy[a]

Low-Dose-Rate Brachytherapy Technique and Trends

The advantage of brachytherapy is a result of the placement of sources directly into the target tissue, and the low energy of the radioactive sources used—only 21 and 28 kiloelectron-volts for ^{103}Palladium and ^{125}Iodine, respectively. This results in rapid dose falloff (a few millimeters) beyond the target volume, and hence a high ratio of target to nontarget dose. This rapid falloff, however, also mandates a high degree of precision in the placement of these sources to ensure that any tumor-bearing regions within the prostate gland are not underdosed.

Beginning in the early 1990s, the number of prostate cancer patients undergoing brachytherapy for low-risk cancers increased dramatically, with the CaPSURE database reporting an increase in the use of brachytherapy from 4% in 1990 to 15% by 2007 (Cooperberg, Broering, Carroll 2010). More recent data indicate that the use of brachytherapy has declined since the early 2000s, with some estimates of as much as a 60% decrease in utilization. Although the reasons for this decline remain open for debate, competition from ultrahypofractionated RT, robotic prostatectomy, and increased patterns of self-referral from urology practices with ownership of linear accelerators are the most frequently suspected causes (Burt et al., 2018; Mitchell, 2013). However, recent comparative efficacy data also suggest that the addition of brachytherapy improves control and survival rates for patients with intermediate- and high-risk localized cancers; it remains to be seen if these new data will reverse the decline in brachytherapy utilization (Morris et al., 2017; Orio et al., 2016).

Computer programs using algorithms with optimization of dosimetric coverage of the entire prostate while minimizing dose to the intraprostatic urethra and rectum are employed for planning and executing brachytherapy (Fig. 157.7). The seeds are implanted in a pattern that employs more seeds toward the outer areas of the gland and fewer seeds toward the center, a pattern termed **peripheral (or modified-peripheral) loading.** This allows for the preferential sparing of the urethra to reduce urinary morbidity (Wallner et al., 1995). Several methods for designing seed placement have been described for permanent radioactive seed implantation. The **preplanned** method popularized by Blasko et al. (1993) in Seattle uses preimplant transrectal ultrasound images obtained preoperatively, with the patient in the same lithotomy position as for the actual implant, to calculate seed placement for an optimal dosimetric plan. Stone and Stock (1999) described a method for determining the number of seeds to be implanted on the basis of the size of the gland and a nomogram reported by Anderson (1976). The seeds are implanted using empirical rules defined by Patterson and Parker in the 1930s (Fletcher, 1980). Kaplan et al. (2000) described a method in which the dosimetric plan is calculated on TRUS images obtained intraoperatively, called **intraoperative planning**. Zelefsky et al. (2000) reported a comparison of implant results using all three of these methods, and found that intraoperative **dosimetry** (distribution of radiation) was associated with superior prostate dose coverage and reductions in average and maximal doses to the urethra. Cystoscopy is often but not always performed with the purpose of removing any blood clots from the bladder, or in rare instances to retrieve any seeds placed inadvertently into the bladder.



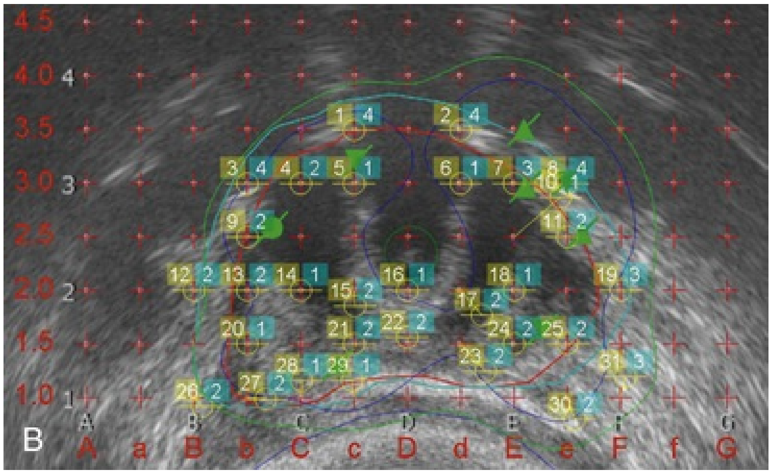


FIG. 157.7 (A) Off-axis view of a brachytherapy treatment plan showing needle paths and seed locations. The prostate *(red),* rectum *(blue),* and urethra *(green)* are shown. Note peripheral loading of seeds to minimize the dose to the central urethra. (B) Axial view of brachytherapy treatment plan superimposed on TRUS image. Seeds that have been placed are denoted by *green triangles with lines.* The grid coordinates superimposed on the TRUS correlate with the holes in the template grid and allow the treatment team to communicate regarding specific seeds/needles.

There are three generally utilized choices of isotope for permanent seed implantation. ^{125}Iodine emits low-energy x-rays at 27 keV, with a half-life of 59.6 days. ^{103}Palladium was introduced in 1986 because it has an energy spectrum similar to that of ^{125}I, with 21-keV x-rays, but with a significantly shorter half-life of 17 days. However, some prefer the slightly higher energy of ^{125}I because it offers “more forgiving” dosimetric properties in terms of ease of achieving good prostatic coverage. The most recently introduced isotope, in use since 2004, is ^{131}Cesium, which emits x-rays at 30 keV (thereby offering dose characteristics similar to ^{125}I), but with a half-life of 9.7 days. Treatments are delivered over a shorter period with ^{131}Cs compared with ^{103}Pd and ^{125}I, with 90% of the dose delivered in 33, 58, and 204 days respectively. The recommended monotherapy (i.e., brachytherapy alone, without EBRT) dose prescription for ^{125}I is 140 to 160 Gy, for ^{103}Pd is 110 to 125 Gy, and for ^{131}Cs is 100–115 Gy. A randomized trial comparing ^{125}I versus ^{103}Pd in patients with early stage, low-grade cancers (stage ≤cT2a, Gleason ≤6, PSA ≤10 ng/mL) found no differences in biochemical control between the two. Urinary symptoms were statistically worse at 1 month for the patients receiving ^{103}Pd (mean AUA symptom score 18.6 vs. 14.8) but then resolved more rapidly, with 6-month mean scores of 9.9 for ^{103}Pd versus 12.0 for ^{125}I, consistent with their differences in half-life (Herstein et al., 2005).

Although outcomes in patients with low-risk prostate cancer using brachytherapy have been demonstrated in numerous series to be generally excellent (see Evaluating the Response to Radiation Therapy), patients with unfavorable intermediate- or high-risk prostate cancer are often managed with a combination of brachytherapy with EBRT. The goal of adding EBRT is to increase the dose to the periprostatic tissues and seminal vesicles, and allow for treatment of lymph nodes if indicated. Also, EBRT may help make up for any regions potentially not receiving an adequate brachytherapy dose because of variations in seed distribution. The total combined dose from brachytherapy plus EBRT is greater than what can be given safely using either modality alone. Typically, when EBRT is to be combined with brachytherapy, a dose of 45 Gy is delivered (compared with 75 to 80 Gy when EBRT is used alone). The dose of the implant boost in such combination therapy is generally 60% to 70% of the dose prescribed for patients treated with implant alone: 108 to 110 Gy for ^{125}I, 90 to 100 Gy for ^{103}Pd, and 80 to 85 Gy for ^{131}Cs (Davis et al., 2012).

Assessment of Permanent Implant Quality

The goal of prostate brachytherapy is to deliver a tumoricidal dose to the prostate while minimizing dose to nearby sensitive normal structures such as the rectum and urethra. Postimplant assessment of dosimetry both within the prostate and in these dose-limiting regions is important to assess implant quality. Postimplantation CT with or without MRI is performed to determine seed locations and calculate the dose received by the prostate and other structures of importance (Fig. 157.8) (Mizowaki et al., 2002; Willins and Wallner, 1997). Commonly utilized and validated parameters of implant quality include but are not limited to the following:

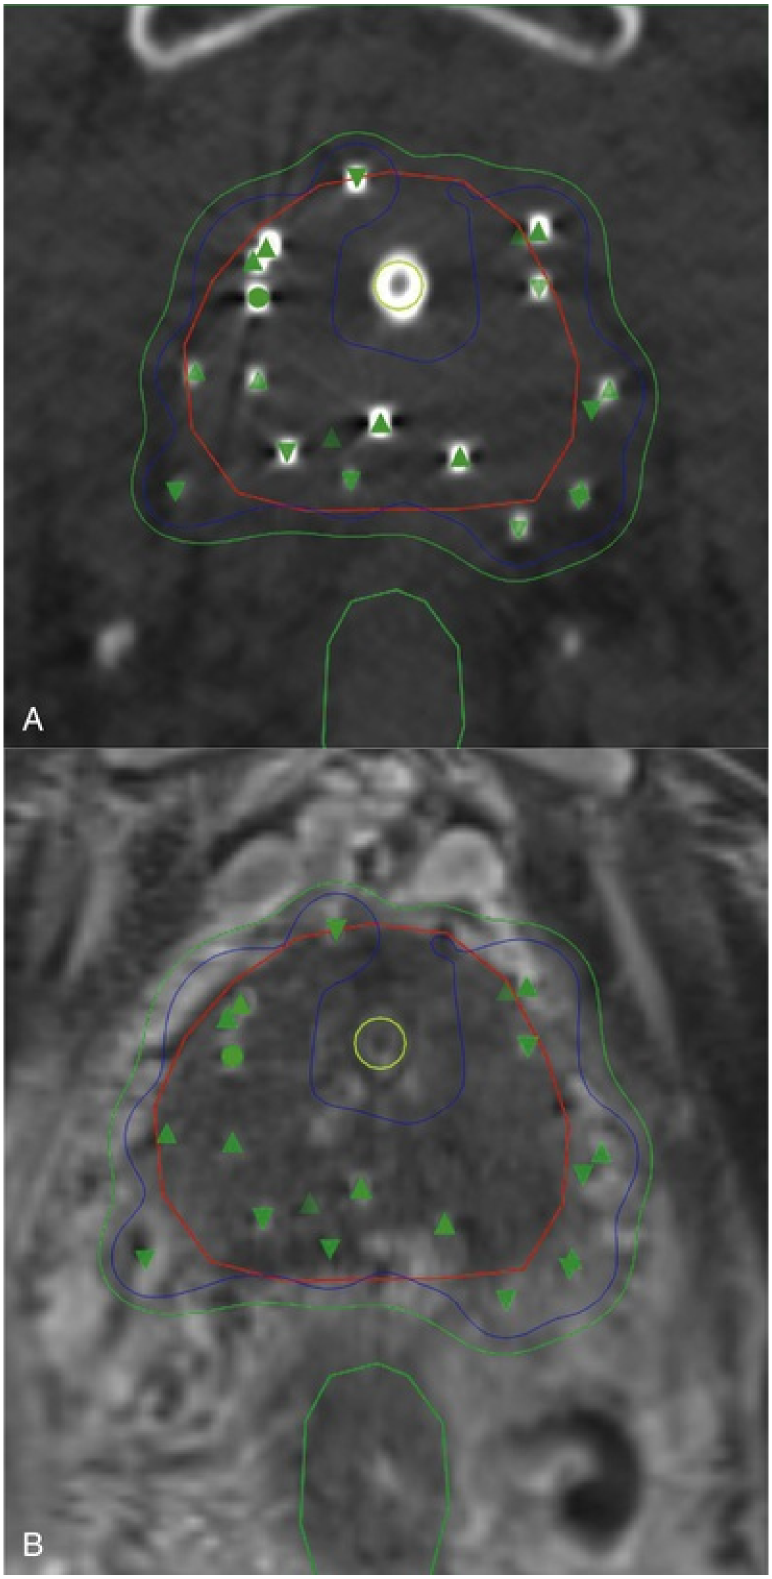

FIG. 157.8 Brachytherapy postimplant computed tomography (CT) (A) and T2 magnetic resonance imaging (MRI) (B) axial images. Seeds are well-visualized on CT, but prostate delineation is obscured by seed artifact. MRI imaging allows for improved prostate delineation. Image sets are

spatially registered/fused for accurate correlation between dose and normal anatomy. The prostate *(red),* urethra *(yellow),* and rectum *(light green)* are shown. 100% and 150% prescription isodose lines are shown in *green* and *blue*, respectively.

- Prostate **D90:** minimum dose received by the “hottest” 90% of the prostate, or alternatively described as the highest isodose line encompassing 90% of the prostate)
- Prostate **V100:** volume of the prostate receiving the prescribed dose (i.e., 100%), expressed as a percentage

The American Brachytherapy Society (ABS) recommends using the prostate D90 and V100 and V150 (the percent volume of the prostate receiving 100% and 150% of the prescribed dose, respectively) as parameters to assess implant quality (Davis et al., 2012). Ideal implant parameters are shown in Table 157.4.

TABLE 157.4

Ideal Permanent Prostate Brachytherapy Postimplantation Guidelines

ORGAN	PARAMETER	CONSTRAINT
Prostate	Dose received by 90% of the prostate volume (D90)	>100% of prescription dose
	Volume of prostate receiving 100% of prescription dose (V100)	>95% of the prostate
	Volume of prostate receiving 150% of prescription dose (V150)	<50% of the prostate
Rectum	Volume of rectum receiving 100% of prescription dose (R100 or RV100)	<1–1.3 cm^3

Data from Nath R, Bice WS, Butler WM et al: AAPM recommendations on dose prescription and reporting methods for permanent interstitial brachytherapy for prostate cancer: Report of Task Group 137. *Med Phys* 36(11):5310–5322.

Since the advent of transperineal brachytherapy, advances in technique and physician experience have resulted in improved dosimetric outcomes. However, factors such as needle deviation during insertion, tissue deformation, intraoperative prostatic edema, and relaxation of tissues and possible source shift after needle removal can result in variations from the idealized dosimetric plan

(Roberson et al., 1997; Stone et al., 2002; Yamada et al., 2003). Edema results in an average 30% increase in prostate size when evaluated at day 1 postimplantation, but can vary anywhere from 15% to 148% (Leclerc et al., 2006). Although edema typically subsides after 2 to 4 weeks, a significant portion of the dose may be already delivered by then, depending on the half-life of the isotope used. Brachytherapy practitioners vary in their preferred timing of postoperative imaging, with most utilizing somewhere between day 0 (date of implant) to day 30. Earlier assessment allows for immediate feedback and "worst-case" determination of prostatic dose coverage, whereas later times allow for resolution of edema with associated improvement in prostate dosimetric values.

PSA control rates after brachytherapy have been well-demonstrated to be related to postimplant dosimetry. Potters et al. evaluated 883 patients with T1 to T2 prostate cancer who underwent brachytherapy, and found that biochemical failure was associated with Gleason score, PSA, and lower prostate D90 (Potters et al., 2003). A multi-institutional analysis of over 2600 patients treated at 11 institutions also found that prostate D90 on postimplant dosimetry was significantly associated with biochemical outcome for both ^{125}I and ^{103}Pd (Zelefsky et al., 2007).

Because of the challenge of reproducibility of implant quality, there has been interest in developing better methods for monitoring source position and edema during the implant procedure. A commercially available and widely utilized method involves updating source positions intraoperatively by marking the position of each source at the time of deposition based on the visible needle tip or source itself on sagittal TRUS view, a technique often termed **real-time or ultrasound dosimetry.** Because this does not update source position after the time of placement, it may not account for tissue or source position changes and/or early edema occurring during the implant. Nag et al. (2008) compared real-time dosimetry to postimplant CT scans and found that despite some correlations between the two, there were large variations in commonly utilized dosimetric reporting parameters, and a tendency for ultrasound dosimetry to underestimate high-dose regions and dose to normal organs.

In contrast with the method described earlier, another approach is to visualize intraprostatic sources using fluoroscopy or in-room CT, which allows for reliable and repeatable imaging over the course of the implant. Termed **dynamic dosimetry,** this approach allows intraoperative continuous monitoring of source positions and plan modification. Westendorp et al. described their experience using a C-arm cone-beam CT unit, in which intraoperative TRUS and CT images were coregistered based on implanted fiducial gold markers, and doses to prostate and urethra evaluated. They reported that in 17% of the procedures, they identified prostatic regions that required dose modification and remedial seeds placed (Westendorp et al., 2017).

Another method for dynamic dosimetry reported by Song et al. (2011) utilizes a nonisocentric fluoroscopy unit, with the advantage of being more readily available than intraoperative cone-beam CT units. When updated dosimetry is desired during the brachytherapy procedure, three fluoroscopic images are acquired and processed to calculate a three-dimensional seed distribution, which is then coregistered to the TRUS images based on seed matching (Kuo et al., 2012; Song et al., 2011). Results from a phase II trial suggest high reliability in achieving excellent prostate dosimetric values utilizing this technique, with 44/45 patients having prostate V100 greater than or equal to 95% (Lee et al., 2018).

High-Dose-Rate Brachytherapy

Permanent seed implantation delivers a dose over a number of weeks to months depending on the isotope chosen, hence the term low-dose-rate (not to be confused with *low dose*). An alternative method of brachytherapy is **high-dose-rate (HDR) brachytherapy,** which delivers short but high doses of radiation using temporary catheters. For HDR brachytherapy, hollow catheters are placed through the perineum into the prostate using the same procedure as for LDR brachytherapy. Imaging and treatment planning are performed based on either CT, MRI, or directly on TRUS used for catheter insertion. Treatment utilizes an iridium-192 (^{192}Ir) source that emits 400-keV gamma radiation, and a single source can be migrated along the length of each catheter at various positions for variable lengths of time on the order of seconds to minutes. The source is manipulated robotically to minimize radiation exposure to medical staff. The radiation dose is delivered in this way over several applications. No postimplantation dosimetry is performed, because no sources are left inside the patient.

Initially, HDR was mostly employed as a boost in combination with EBRT for patients with intermediate- or high-risk features. Most recently, it has become more common to also use it as monotherapy in patients with low-risk disease.

There are some potential advantages and disadvantages of HDR versus LDR brachytherapy, summarized as follows:

Potential advantages for HDR versus LDR brachytherapy include:

- The use of catheters allows for more ready inclusion of extracapsular disease and seminal vesicles, if desired.
- There is greater opportunity for dose optimization by modifying dwell times and positions of the source within the catheters.
- The use of high doses per fraction has a potential biologic dose advantage for prostate cancer if a low alpha/beta ratio exists.
- No need for personnel to handle the radioactive source during treatment.
- The use of a single source for all patients using a multipurpose facility makes HDR brachytherapy potentially more cost-effective.

Potential disadvantages for HDR versus LDR brachytherapy include:

- There are potential treatment inaccuracies caused by catheter and organ/patient movement between imaging and time of source insertion (during treatment planning) or between fractions, interobserver contouring variabilities, and effects of edema (De Brabandere et al., 2012; Foster et al., 2011; Kawakami et al., 2014; Mullokandov and Gejerman, 2004; Whitaker et al., 2011; Yoshida et al., 2010)
- Established fractionation regimens with long-term results employ multiple fractions (with 6-hour interfraction intervals) and/or more than one catheter implant session, resulting in less patient convenience and more logistical and quality assurance workload per patient.
- The relatively high activity and energy of the ^{192}Ir source requires availability of a shielded room for treatment delivery.
- There are less favorable pathologic response results from available post-treatment biopsy studies (Kestin et al., 2002a; Stone et al., 2010).

- No comparable randomized phase III data exist to support the efficacy of HDR in high-risk prostate cancer.

High Dose Rate as a Boost With External Beam Radiation Therapy

There are a wide range of EBRT target volume treatment schedules reported in the literature, and published schedules include the following (Hoskin et al., 2013):

- 45 Gy in 25 fractions over 5 weeks
- 46 Gy in 23 fractions over 4.5 weeks
- 35.7 Gy in 13 fractions over 2.5 weeks
- 37.5.Gy in 15 fractions over 3 weeks

HDR brachytherapy doses that have been prescribed with these schedules include the following:

- 15 Gy in 3 fractions
- 11 to 22 Gy in 2 fractions
- 12 to 15 Gy in 1 fraction

High-Dose-Rate Monotherapy

HDR monotherapy regimens utilizing multiple fractions and/or multiple implant sessions (~4 to 6 fractions) have the longest follow-up and have been associated with low acute toxicity and high biochemical control rates in the series published to date. Published schedules that have been used include the following:

- 34 Gy in 4 fractions
- 36 to 38 Gy in 4 fractions
- 31.5 Gy in 3 fractions
- 26 Gy in 2 fractions

Whether single-fraction HDR brachytherapy is also feasible has been evaluated in recent studies. Krauss et al. (2018) reported results of a trial utilizing a single 19-Gy fraction of HDR brachytherapy, but the 5-year biochemical control rate was a disappointing 73.9%, with no significant difference between low- and intermediate-risk patients. Biopsy-proven local failure at 5 years was 19%, occurring at median of 3.9 years post-treatment. Another trial by Morton et al. (2017) randomized patients to either 19 Gy in a single fraction versus a 2-fraction regimen using 13.5 Gy per fraction. At median follow-up of 27 months, 7/87 patients in the single-fraction arm had relapsed biochemically, most of whom were found to have local recurrence. In the 2-fraction arm, one patient developed biochemical failure and was found to have distant metastases. These results suggest that either single-fraction doses greater than 19 Gy are required, or continued use of fractionation in HDR is necessary.

No randomized trials directly comparing HDR versus LDR brachytherapy have been performed. Using the SEER Medicare database, Tward et al. (2016) compared the incidence of grade 3 adverse events after LDR and HDR brachytherapy, and after LDR plus EBRT and HDR plus EBRT. At 8 years, the propensity-weighted cumulative adverse event incidence was highest after HDR plus EBRT (26.6%) and lowest after LDR alone (15.7%). The absolute excess risk over nontreated controls at 8 years was 1.9%, 3.8%, 8.4%, and 12.9% for LDR, HDR, LDR plus EBRT, and HDR plus EBRT, respectively. No statistically significant differences were observed between LDR and HDR.

Patient Selection for Brachytherapy

The major acute toxicity of brachytherapy is obstructive and irritative uropathy, with a low but non-negligible risk of need for temporary catheterization. This is a major consideration in determining the eligible patient population for brachytherapy.

The American Brachytherapy Society and Groupe Européen de Curiethérapie (GEC) and the European Society for Radiotherapy & Oncology (ESTRO) have published consensus guidelines regarding LDR and HDR brachytherapy, respectively (Davis et al., 2012; Hoskin et al., 2013). Patient inability to undergo general anesthesia is considered a contraindication to brachytherapy. Although published reports have described use of local anesthesia for the procedure, the majority of experience is with patients having general anesthesia, which minimizes the risk for patient movement disrupting the spatial accuracy of the procedure (Wallner, 2002).

Other relative contraindications include the following:

- Large TURP defects, or TURP within prior 3 to 6 months (some association with increased risk for urinary incontinence and/or technical challenges (Talcott et al., 2001)
- Factors associated with poor urinary outcomes or obstruction (Martens et al., 2006)
  - Maximum urinary flow rate (Qmax) less than 10 mL/s
  - International Prostate Symptom Score greater than 20
  - Large median lobe hypertrophy (Nguyen et al., 2002)
- Prior pelvic RT
- Connective tissue disease or inflammatory bowel disease
- Pubic arch interference (inability to access anterior/lateral prostate with needles)
- Lithotomy position not possible
- Rectal fistula or lack of TRUS access (e.g., patient who has abdominoperineal resection)

Patients with large glands or median lobe hypertrophy may be treated with androgen suppression to reduce gland size before brachytherapy, using either luteinizing hormone–releasing hormone (LHRH) analogues or androgen receptor blockade. Approximately 30% gland shrinkage may be achieved with these drugs (Kucway et al., 2002; Merrick et al., 2006). However, the morbidity associated with LHRH analogues is well-described (Bosco et al., 2015; Tsai et al., 2015) and has specifically been correlated with increased cardiovascular mortality in patients who were treated for gland downsizing before brachytherapy (Nanda et al., 2013). Recently, Bae et al. (2018) described their results utilizing 5α-reductase inhibitors for this purpose, thereby avoiding the negative effects of LHRH analogues or androgen blockers. Although less robust gland size reduction was achieved (approximately 20%), this may be considered as a less morbid alternative to the other regimens.

Of note, unlike with EBRT, the value of androgen suppression combined with brachytherapy is unproven by randomized trial data and remains a subject of some controversy. Although its use in patients with high-risk disease receiving brachytherapy or brachytherapy plus EBRT is generally accepted, the role of ADT is unclear, particularly among patients receiving brachytherapy for unfavorable intermediate-risk disease or even high-risk disease with limited risk factors (Keyes et al., 2017).

Brachytherapy Combined With External Irradiation

Although outcomes in patients with low-risk prostate cancer using brachytherapy alone are excellent and brachytherapy alone is well-proven and established, the potential benefit of combining EBRT with brachytherapy for patients with intermediate-risk disease has been debated. EBRT is employed in these patients to treat the prostate and periprostatic tissues. This strategy allows targeting of high-risk areas outside the prostatic capsule and increases the dose to the prostate itself. Typically, a dose of 4500 cGy of conventionally fractionated EBRT is delivered (compared with 7560 to 7920 cGy when EBRT is used alone). The dose of the implant boost in such combination therapy is generally 60% to 70% of the dose prescribed for patients treated with implant alone.

Merrick et al. (2017) pooled results from two randomized trials evaluating the role of supplemental EBRT in patients with higher-risk features. Patients were stratified into unfavorable intermediate (primary Gleason pattern 4, ≥50% positive biopsies, or ≥2 irradiation features), favorable intermediate, and high-risk cohorts. The median follow-up was 7.5 years. The 10-year biochemical failure for favorable intermediate, unfavorable intermediate, and high risk was 1.7%, 6.6%, and 15.5%, respectively ($P < 0.001$). Although unfavorable intermediate-risk patients had a greater incidence of PSA relapse and disease-specific mortality when compared with favorable intermediate-risk patients, neither the addition nor dose of supplemental EBRT influenced outcome.

RTOG 02-32 was another randomized trial that evaluated patients with intermediate risk to determine if there was a benefit derived from adding 45 Gy of EBRT to brachytherapy. At an interim analysis, of the required 443 patients with 5 years of follow-up, the 5-year progression-free survival was 85% for the EBRT + brachytherapy arm and 86% for the brachytherapy alone arm (hazard ratio [HR] 1.02), indicating no improvement. However, it should be noted that the study population was predominantly patients with favorable intermediate-risk disease, and therefore the study is not conclusive regarding the value of combined therapy in patients with more unfavorable disease (Prestidge et al., 2016). Also, both trials allowed physician discretion regarding the use of androgen suppression, and therefore this remains a potential confounding factor.

Whereas brachytherapy alone is accepted in general for low- and favorable intermediate–risk cancers, biochemical control is considered to be improved for high-risk patients, and possibly for unfavorable intermediate–risk patients, by combining brachytherapy with EBRT (Spratt and Zelefsky, 2013; Spratt et al., 2017a). Biochemical disease–free survival for high-risk men using this strategy can range from 80% to 90%, particularly when combined with ADT (Koontz et al., 2009; Merrick et al., 2011; Shilkrut et al., 2013a, 2013b; Taira et al., 2010). HDR brachytherapy series with at least 5 years of follow-up also show very good biochemical control for both intermediate-risk (83% to 100%) and high-risk (74% to 91%) patients (Morton and Hoskin, 2013). In the ASCENDE-RT trial, men with high-risk disease were treated with 12 months of ADT and pelvic irradiation to 46 Gy followed by either an EBRT boost to 78 Gy or an LDR brachytherapy boost. At a median follow up of 6.5 years, men who received an EBRT boost were twice as likely to experience biochemical failure compared with men who were treated with the brachytherapy boost (HR 2.04; $P = .004$). However, there was no significant difference in overall survival between the two treatment arms (Morris et al., 2017).

Recent pooled retrospective analyses suggest that patients with very-high-risk prostate cancers have improvements not only in biochemical control, but also in disease-specific survival with this approach. Kishan et al. (2018) analyzed 1809 men treated for Gleason 9 to 10 cancer at 12 centers between 2000 and 2013. Of 1809 men, 639 underwent RP, 734 underwent EBRT, and 436 underwent EBRT + brachytherapy. The adjusted 5-year disease-specific mortality rates were RP, 12%; EBRT, 13%; and EBRT + brachytherapy, 3% (95% confidence interval [CI], 1% to 5%). EBRT + brachytherapy was associated with significantly lower disease-specific mortality than either RP or EBRT (cause-specific HRs of 0.38 and 0.41). EBRT + brachytherapy was also associated with a significantly lower rate of distant metastasis (propensity-score–adjusted cause-specific HRs of 0.27 for RP and 0.30 for EBRT) (Kishan et al., 2018).

Key Points: Brachytherapy

- Prostate brachytherapy can be performed using either LDR (permanent implant) or HDR (temporary catheter) approaches.
- Postimplant dosimetry after LDR brachytherapy is important to assess implant quality.

- Dosimetric measures such as prostate V100 and D90 are used to describe adequate dose coverage of the prostate.
- Patients who have preexisting obstructive uropathy (IPSS >20 or Qmax <10 cc/s) are relatively contraindicated for brachytherapy.
- Combined brachytherapy and EBRT is not indicated for patients with low-risk disease, but is supported by data for a role in the management of high-risk disease.

Androgen Suppression Combined With Radiation

Background and Potential Mechanisms

In 1941, Huggins and Hodges (1941) reported the androgen-dependent nature of prostate cancer. This seminal work provided, in part, the rationale for the use of hormonal therapy as an adjunct to RT in the definitive management of local and locally advanced prostate cancer. As early as 1967, hormonal therapy was being added to RT in an attempt to modify the outcomes of patients with stage C (T3) prostate cancer (del Regato, 1967). Such T3 tumors were often quite large, and cytoreductive ADT provided more favorable geometry for external irradiation, and reduction in tumor burden (Green et al., 1984). However, the use of hormonal therapy in combination with radiation remained controversial throughout the 1970s and 1980s as radiation techniques were improving, and results from early series evaluating the benefit of ADT with radiation were often negative (Neglia et al., 1977). In one of the earliest favorable reports, Pilepich et al. reported that patients with histologically unfavorable lesions treated on the RTOG 75-06 trial and who had received androgen suppression and EBRT had similar disease-free survival and overall survival as patients with more favorable tumors who did not receive androgen suppression (Pilepich et al., 1995).

Combined-modality approaches are well-established in the treatment of many types of cancer. Androgen-responsive prostate cells undergo programmed cell death (apoptosis) when deprived of androgens (Denmeade et al., 1996; Furuya et al., 1995). Similar to radiation, this death does not appear to be p53-dependent (Furuya et al., 1995). Recently, Tarish et al. (2015) used pre- and post-treatment biopsies in 48 patients to monitor molecular responses to AST and RT. They found that castration impaired nonhomologous end joining repair of DNA double-strand breaks, with reduced amounts of the repair protein Ku70 and higher amounts of residual unrepaired double-strand breaks from radiation. Similarly, Al-Ubaidi et al. (2013) showed that castration reduced Ku70 protein levels in prostate cancer biopsy samples. These results offer an explanation for the enhanced radiosensitivity of prostate cancer after castration.

Spratt et al. (2015) also showed that androgen receptor expression and activity are durably upregulated after RT in multiple human prostate cancer models in vitro and in vivo. The degree of androgen receptor upregulation correlated with survival in vitro and time to tumor progression in animal models. Androgen receptor pathway upregulation, measured by a rise in serum levels of androgen receptor–regulated hK2 protein, was found in nearly 20% of patients after RT, and these men were threefold more likely to experience subsequent biochemical failure. Their data suggest that the value of adjuvant ADT after RT is through mitigation of RT-induced upregulation of androgen receptor signaling.

Androgen Suppression Therapy and Localized Disease

Several prospective randomized studies have investigated the role of ADT with radiation for men with intermediate- to higher-risk localized prostate cancer relative to radiation alone (D'Amico et al., 2008; Denham et al., 2011; Jones et al., 2011; Pisansky et al., 2013; Zapatero et al., 2015). As outlined in Table 157.5, trials have investigated radiation alone versus radiation in combination with androgen suppression and the duration of hormonal therapy with the radiation.

TABLE 157.5

Selected Randomized Controlled Trials Investigating the Use of Androgen Suppression Therapy With Radiation

STUDY	TNM STAGE (%)	GLEASON SCORE (%)	*N*	MEDIAN FOLLOW-UP (YEARS)	TREATMENT ARMS	OVERALL SURVIVAL: %	P C S M %

The Trans-Tasman Radiation Oncology Group (TROG) performed a three-arm randomized trial comparing RT alone to RT plus 3 or 6 months of androgen suppression for 818 men with T2b to T4 disease (Denham et al., 2011). With 10.6 years of follow-up, the 6-month arm showed significant improvements in disease-free, metastasis-free, disease-specific, and overall survival relative to RT alone. D'Amico et al. studied 206 men, all with clinical T1 to T2 disease and followed them for a median of 7.6 years (Boorjian et al., 2008; D'Amico et al., 2008). Their median PSA was 11 ng/mL, and 73% had a Gleason score of 7 or greater. Benefits in both overall and disease-specific survival were noted. Of note, it appeared that the survival benefit may have been limited to only those men with no or minimal comorbid illness.

RTOG 94-08 randomized 1979 men with T1b to T2b and PSA less than 20 ng/mL disease to RT alone versus RT with 4 months of combined androgen blockade (Jones et al., 2011). With a median follow-up of 9.1 years, the 10-year overall survival was 62% in the arm with androgen suppression compared with

57% in the RT alone arm. In unplanned subgroup analyses, it appeared that the 54% of men with intermediate-risk disease derived the greatest benefit, with the low-risk group (35%) showing no significant benefit to hormonal therapy.

DART01/05 randomized 178 men with T1c to T3 intermediate- or high-risk prostate adenocarcinoma receiving radiation to either 4 months of short-term ADT or 24 months of long-term ADT (Zapatero et al., 2015). The 5-year overall survival with long-term ADT was 95% compared with 86% in the short-term group. In the subgroup analysis by risk group, the benefit in overall survival was more evident for patients with high-risk disease, but not for those with intermediate-risk disease.

Androgen Suppression Therapy and Locally Advanced Disease

Several trials have also evaluated the role of ADT with RT for patients with locally advanced or high-risk cancers, and identified beneficial effects on biochemical control and overall survival.

In RTOG 86-10, 456 patients with large (25 cm^3), stage T2b to T4, Nx tumors who were randomly assigned to 4 months of total androgen suppression with RT given after the first 2 months had improved local control, disease-free survival, and freedom from metastases compared with patients receiving 65 to 70 Gy of RT alone (Roach et al., 2008). At a median follow-up of over 12 years, the 10-year overall survival rates were no different between the two arms, but there was a significant improvement in disease-specific mortality of 36% versus 23% ($P = .01$).

In EORTC 22863, a phase III trial of androgen suppression, Bolla et al. (2010) reported an overall survival advantage for patients receiving 3 years of goserelin starting at the initiation of RT over RT to 70 Gy alone. More than 90% of the 415 patients had either T3 or T4 disease, and the remainder were eligible as a result of high-grade tumors. With 9.1 years of follow-up, there were significant improvements in both overall survival and disease-specific survival with the addition of androgen suppression.

A meta-analysis of prospective trials of ADT in nonmetastatic prostate cancer showed a 30% reduction in relative risk for disease-specific mortality and a 14% reduction in the relative risk for all-cause mortality with the use of ADT (Nguyen et al., 2011).

Benefit of Radiation in Addition to Androgen Suppression for Locally Advanced Disease

Two multicenter randomized trials have investigated the opposite question, of whether the addition of RT improves outcomes for men with locally advanced, nonmetastatic disease when treated with primary androgen suppression (Warde et al., 2011; Widmark et al., 2009). In the first trial, 875 men with a PSA of 70 ng/mL, N0, M0, and mostly T3 disease were randomized to 3 months of combined androgen blockade followed by lifelong flutamide with or without 70 Gy of RT. After a median of 7.6 years of follow-up, trial investigators reported a relative risk for disease-specific death of 0.44 (95% CI, 0.30 to 0.66, $P < .001$), favoring the addition of RT (Widmark et al., 2009).

In the study conducted by the NCI of Canada, 1205 men with mostly T3 and T4 disease were randomized to lifelong androgen suppression with or without 65 to 69 Gy of RT. With a median of 6 years of follow-up, an HR of 0.54 (95% CI, 0.27 to 0.78) for disease-specific survival favored the RT + ADT arm. The overall survival at 7 years was 74% (95% CI, 90 to 78) for the combined arm versus 66% (95% CI, 60 to 70) for the arm with androgen suppression alone (Warde et al., 2011).

In the STAMPEDE trial of men with newly diagnosed, locally advanced, or metastatic disease or those with relapsing disease and poor prognostic features, use of 24 months of ADT plus abiraterone and prednisolone as compared with ADT alone was associated with a 71% relative improvement in the time to treatment failure and a 37% difference in overall survival. The addition of radiation beginning 6 to 9 months after randomization was mandatory for patients with node-negative disease and was encouraged for patients with node-positive, nonmetastatic disease (James et al., 2017).

Optimal Duration of Androgen Suppression

Evaluation of the optimal type, timing, and duration of androgen suppression in combination with RT has been the subject of several trials.

In RTOG 99-10, which randomized 1490 men, 84% of whom had intermediate-risk disease, to 4 versus 8 months of neoadjuvant and concurrent androgen suppression with radiation, no advantage was identified in biochemical control or overall survival to longer course treatment (Pisansky et al., 2013). NCCN guidelines recommend a duration of 4 to 6 months of ADT for patients with unfavorable intermediate-risk cancers, and none for patients with favorable intermediate-risk disease (Mohler et al., 2016).

Other studies have investigated duration of androgen suppression among men with higher risk disease. In RTOG 92-02, 1521 patients with stage T2c to T4, N0 to N1, M0 disease were randomly assigned to 4 months of total androgen suppression with radiation administered after 2 months, or the same regimen followed by an additional 2 years of goserelin (Horwitz et al., 2008). A hypothesis-generating subgroup analysis revealed significant improvement in overall survival, 80% versus 69%, and disease-specific survival, 90% versus 78%, in patients with Gleason grade 8 to 10 tumors.

The EORTC randomized 970 men who had received 6 months of combined androgen blockade and RT to no further androgen suppression versus 30 months of an LHRH analogue (Bolla et al., 2009). Powered as a noninferiority study, at 6.4 years of follow-up, the 5-year cause-specific mortality was 4.7% (95% CI, 2.7 to 6.7) versus 3.2% (95% CI, 1.6 to 4.8), favoring long-term hormonal therapy. The DART01/05 GICOR trial showed similar results when comparing 24 months of ADT to 4 months of ADT with EBRT. The 5-year biochemical disease–free survival, metastasis-free survival, and overall survival benefit to long-term ADT was more evident in the patients with high-risk disease (Zapatero et al., 2015).

In a study investigating RT with 18 months relative to RT with 36 months of goserelin for men with T3 to T4, PSA greater than 20 ng/mL, or Gleason 8 to 10 disease, Nabid et al. (2018) reported that with 9.4 years of follow-up, there was no difference in survival between the groups and 18 months was associated with significantly better quality of life.

Currently, NCCN guidelines recommend a total duration of 24 to 36 months for patients with high-risk or very-high-risk prostate cancer when treated with EBRT, or 12 to 36 months when treated with combined brachytherapy + EBRT (Mohler et al., 2016).

Key Points: Radiation Therapy and Androgen Suppression Therapy

- Randomized controlled trials have shown a survival benefit to the combination of radiation and hormonal therapy relative to either radiation or hormonal therapy alone for men with intermediate- to high-risk disease.

- For men with locally advanced, high-risk disease, 28 to 36 months of hormonal therapy appears superior to 4 to 6 months for reducing death from prostate cancer.

Role of Prophylactic Pelvic Nodal Treatment

Given that the pelvic lymph nodes are a natural route of spread for prostate cancer, there has been understandable interest in the potential for prophylactic nodal radiation to reduce the recurrence rates of intermediate- and high-risk cancers.

The question of timing of hormonal therapy and impact of radiation field size was addressed by RTOG 94-13, a four-arm study comparing whole-pelvis versus small-field radiation with 4 months of either neoadjuvant or adjuvant total androgen suppression. Eligible patients had adverse risk factors, with estimated risk for positive-node disease of more than 15%. A difference was initially seen in progression-free survival at 4 years, 54% versus 47% for the whole-pelvis versus prostate-only radiation, respectively ($P = .022$), but no difference was seen in overall survival (Roach et al., 2003). An update of this study showed a loss of this benefit in biochemical control, highlighting the need for additional studies investigating the inclusion of nodal volumes in men with a high risk for lymph node involvement (Lawton et al., 2007).

GETUG-01 asked a similar question regarding the benefit and toxicity of pelvic normal irradiation in nonmetasatic T1b to T3 N0 prostate cancer patients. Patients were randomized to either pelvic and prostate radiation or prostate-only radiation. The addition of 6 months of neoadjuvant ADT was allowed for patients in the high-risk group. The 5-year progression-free survival and overall survival was similar between the two groups (Pommier et al., 2007). There were no significant differences between acute and late GI toxicities or quality-of-life scores.

Although randomized clinical trials have not shown a benefit to pelvic radiation, there have been retrospective studies that have suggested a benefit (Aizer et al., 2009; Pan et al., 2002). A retrospective study by Aizer et al. (2009) compared 277 consecutive patients with at least a 15% likelihood of lymph node involvement who had undergone either whole-pelvis radiation or prostate-only radiation. After adjusting for confounding variables, the use of whole-pelvis RT predicted biochemical disease–free survival. Patients who received whole-pelvis RT had an increased risk for acute GI toxicity, but no difference in acute GU toxicity or late toxicity. In a study of 234 patients treated with VMAT to either prostate-only or whole-pelvis radiation, at 24-month follow-up bowel-related and urinary health–related quality of life were similar between the two groups (Ishii et al., 2018).

It has been suggested the reason past randomized trials have not shown a benefit of pelvic radiation may be partly a result of undercoverage of superior pelvic lymph node basins given that superior fields ended at S1/2 and L5/S1 (Morikawa and Roach, 2011). In a study examining patterns of pelvic recurrence in men with localized prostate cancer treated with prostate-only RT, the common iliac lymph node station was involved in 55% of patients who experienced a first recurrence in the pelvic lymph nodes (Spratt et al., 2017c). Using a conventional pelvic field at L5/S1 would have only fully covered 42% of the first recurrences among these patients, but extending the field to cover the common iliac station would increase coverage to 93%. The current open randomized trial assessing the benefit of whole-pelvis RT (RTOG 09-24) recommends that the superior border of the pelvic field be at the level of the L4/L5 vertebral disk (National Institutes of Health, n.d.).

Key Point: Role of Prophylactic Nodal Radiation

- Prophylactic pelvic nodal RT has not been shown to improve disease recurrence rates in randomized trials.

Treatment Morbidity and Quality-of-Life Outcomes

For many years, a radiation dose of 70 Gy was considered the maximum that could be safely delivered. With the advent of conformal RT and the ability to visualize and improve targeting of the prostate and to visualize and improve avoidance of surrounding organs, higher-dose RT was made possible, with acceptable rates of treatment-related morbidity. However, further studies that demonstrated an association between radiation doses to organs and treatment-related morbidity presented opportunities for further improvement. For example, in the MD Anderson Cancer Center trial, the 5-year freedom from a complication above grade 2 was 26% in the 78-Gy arm and 12% for the 70-Gy arm, nicely demonstrating the relationship that can exist between dose and complications. When further analysis was performed to identify factors other than total dose that might be used to predict for rectal toxicity, it was shown that the risk for complications increased from 25% to 46% when the rectal volume exposed to 70 Gy increased from less than 25% to greater than 25% (Pollack et al., 2002b). Therefore, technologies such as IMRT that can reduce radiation doses to these organs have the potential of reducing side effects associated with RT, which in general include GI and GU toxicity.

Tables 157.6 and 157.7 summarize acute and late toxicity rates in published series comparing conformal radiation and IMRT for prostate cancer. Consistently in these series, IMRT was associated with lower rates of acute and late GI toxicity, but not GU toxicity, compared with 3D-CRT, despite being used to give higher doses to the prostate. Therefore, advances in radiation technology have simultaneously allowed a higher radiation dose to be given while resulting in lower toxicity.

Several studies have suggested increases in GI and GU toxicity when utilizing combined brachytherapy + EBRT as compared with either modality alone, although this finding is not universal for all analyses (Merrick et al., 2017; Spratt et al., 2017a). Given the benefits of this combined approach may be partially offset by enhanced risk for morbidity, patients being considered for a combination approach should be appropriately counseled (Lee et al., 2007; Tward et al., 2016).

Rectal Toxicity and Management

Acute minor rectal symptoms secondary to RT are usually self-limited. **Late rectal toxicity,** specifically rectal bleeding secondary to radiation proctitis, often occurs between 6 and 18 months after completion of treatment. Proctitis can be a minor, self-limited side effect of radiation treated with steroid suppositories (Someya et al., 2014) or sucralfate enemas (Kochhar et al., 1999). However, for a small percentage of patients, there can be a major toxicity requiring procedural intervention such as argon plasma coagulation (APC), hyperbaric oxygen (Bennett et al., 2012), or in the worst cases diverting colostomy. A retrospective review of 35 patients treated with APC for radiation proctitis found eventual bleeding control in 85.7% of patients, but with 22.9% of patients having post-APC ulceration and a 5.7% risk for colovesicular fistula formation.

A large series of IMRT patients from Memorial Sloan Kettering Cancer Center found 10-year actuarial rates of grade 2 or greater GI toxicity with IMRT to 81 Gy of 5%, with less than 1% of patients developing grade 3 toxicity (Zelefsky et al., 2008a). In a more recent update of this series, patient outcomes of those who received IMRT with image guidance (implanted fiducial markers) were compared with those who received IMRT without image guidance. Rates of grade 2 or greater GI toxicity were low in both groups (1.0% vs. 1.6%, respectively; *P* = .81) (Zelefsky et al., 2012).

Patient-reported outcomes complement toxicity assessment by physicians to provide a fuller picture of a patient's experience after treatment. In one study, 292 patients with a median age of 69 years who received either CRT or IMRT were followed prospectively using the validated EPIC instrument (Sanda et al., 2008). Patients reported acute bowel symptoms that recovered over time including rectal urgency (18% at 2 months compared with 3% at baseline) and frequency (16% at 2 months compared with 2% at baseline), which partially recovered with longer time points of assessment. Analysis of patient-reported outcomes in the ProtectT trial found that treatment of localized prostate cancer with CRT, as compared with active monitoring or RP, was associated with higher bowel bother scores and decreased quality of life because of bowel habits (Donovan et al., 2016). This was most pronounced at 6 months after treatment, with gradual improvement thereafter, but with residual increase in likelihood of bloody stools 2 to 6 years after radiation. No significant differences were seen in the frequency of loose stools or incontinence of stool.

The incidence of all significant rectal complications after brachytherapy has been reported to be 1% to 2% (Barkati et al., 2012; Zamboglou et al., 2013), with a rate of rectal bleeding of approximately 1% (Mohammed et al., 2012; Zelefsky et al., 1999). Studies evaluating comparative morbidity between treatments have confirmed that rates of GI complications are lower than those observed for EBRT (Chen et al., 2017). However, recto-urethral fistula is a rare but feared complication after brachytherapy. A postimplantation colostomy rate of 0.3% was observed in a study of Medicare claims (Benoit et al., 2000a, 2000b). The rate of rectal complications from brachytherapy is correlated with the dose and the volume of rectum receiving a high dose. Merrick et al. (2003) reported that rectal complications were rarely observed when the rectal wall received 85% of the prescribed dose. For brachytherapy alone, a rectal V100 of less than 1.0 cc (if day 1 dosimetry) or less than 1.3 cc (if day 30 dosimetry) is generally recommended (Davis et al., 2012).

Shiraishi et al. evaluated patients receiving combined brachytherapy and EBRT, and correlated risk for bleeding with rectal V100 of greater than 0.5 cc, and EBRT rectal V30 of greater than 35%. Patients who met both dose criteria had a grade 2 rectal bleeding incidence of 4.2% (Shiraishi et al., 2011).

Rectal-Sparing Strategies

As discussed earlier, improvements in the precision of delivery of RT to the prostate while avoiding organs at risk have resulted in decreases in rectal toxicity. Additional approaches to decreasing rectal dose and toxicity include precise delineation of the anorectal volume using MRI, endorectal balloon placement, and implantation of a saline-filled balloon between the prostate and rectum (Gez et al., 2013; Wortel et al., 2017). The most widely reported contemporary approach for decreasing rectal toxicity by lowering rectal radiation dose involves creating physical separation between the prostate and the anterior rectal wall through implantation of a biodegradable hydrogel spacer (Fig. 157.9). In cadaveric experiments, Susil et al. demonstrated that hydrogel spacer could be accurately placed into Denonvilliers’ fascia via a transperineal needle approach, with histologic confirmation of anatomic separation between the prostate and rectum (Susil et al., 2010). This strategy has been shown to be safe and well-tolerated for patients receiving LDR or HDR brachytherapy (Beydoun et al., 2013; Nguyen et al., 2013), EBRT (Mariados et al., 2015; Song et al., 2013), or combination therapy (Yeh et al., 2016) and can be implemented either before treatment initiation or in response to suboptimal dosimetry after a permanent brachytherapy implant. In a multi-institutional study of 222 men with clinical T1 to T2 prostate cancer randomized to spacer injection versus no injection and subsequently treated with IG-IMRT to 79.2 Gy, late rectal toxicity was significantly lower in the spacer group (2.0% vs. 7.0%, $P = 0.04$) (Mariados et al., 2015).

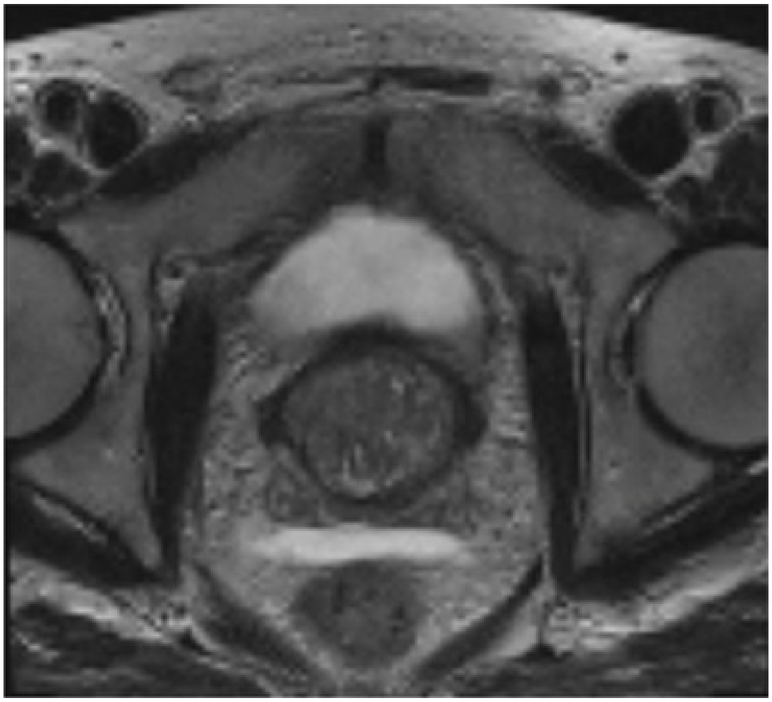

FIG. 157.9 Axial view of MRI T2 image showing hydrogel positioned between the prostate/seminal vesicles and the rectum.

Urinary Toxicity and Management

In the Memorial Sloan Kettering series, the 10-year rate of grade 2 or greater urinary toxicity was 20% with IMRT; grade 3 GU toxicity was rare (Spratt et al., 2013; Zelefsky et al., 2008a, 2012). Patients who received IMRT with image guidance had lower rates of late GU toxicity (3-year rates of grade ≥ 2 toxicity: 10.4% with image guidance vs. 20.0% without, $P = .02$). Sanda et al. (2008) observed that at 2 months after RT, 12% of patients reported dysuria (compared with 1% at baseline), 23% reported weak stream (13% baseline), and 34% reported urinary frequency (16% baseline); symptoms improved by 6 months and were back to baseline levels by 12 months. Urinary incontinence was uncommon after RT. Secondary analysis of urinary toxicity in men receiving prostate CRT on RTOG 94-08 (Mak et al., 2016) identified acute grade ≥2 and ≥3 toxicity in 30.8% and 3.8% of patients, respectively. Late grade ≥2 and ≥3 urinary toxicity at 5 years was 18.3% and 3.3%, respectively. These results were contrasted against the RTOG 96-01 in which men who received post-prostatectomy RT experienced lower rates of acute grade ≥2 at 14%, but similar acute grade ≥3 and late grade ≥2 and ≥3 urinary toxicity.

After brachytherapy, the International Prostate Symptom Score (IPSS) tends to increase significantly immediately after implantation and then decrease at a rate that depends on the half-life of the isotope used (Kollmeier et al., 2012; Sanda et al., 2008). In series of permanent implants, the rate of chronic grade 2 or greater urinary toxicity is approximately 20% (Buckstein, et al., 2013; Mohammed et al., 2012). The use of α-blockers before implantation may decrease the severity and duration of urinary symptoms (Merrick et al., 2002c). Wallner et al. (1995) reported the risk for urinary toxicity to be a function of the length of the urethra receiving a high dose. Grade 2 to 3 morbidity was observed when 20 mm + 11 mm of the urethra received more than 400 Gy with ^{125}I implants. Larger prostatic volumes—specifically, glands greater than 60.0 cm^3—also were associated with higher rates of urinary toxicity. Terk et al. (1998) reported on 251 patients using the IPSS to assess urinary function before and after ^{125}I or ^{103}Pd implantation. Patients with a pretreatment IPSS above 20 demonstrated a 29% risk for developing urinary retention, and a pretreatment score less than 10 was associated with only a 2% risk. For HDR, brachytherapy appears to show a similar pattern, with 15% to 18% showing grade 2 or greater acute urinary symptoms and low rates of chronic grade 3+ urinary morbidity (5% to 10%) (Barkati et al., 2012; Zamboglou et al., 2013).

In the ASCENDE-RT trial (Rodda et al., 2017), men treated with pelvic RT to 46 Gy followed by an LDR brachytherapy boost experienced significantly higher 5-year cumulative rates of grade 3 urinary toxicity as compared with patients treated with EBRT to 78 Gy (18.4% vs. 5.2%, $P < 0.001$).

Brachytherapy after TURP has been associated with increased risk for **urinary incontinence** in some studies, whereas incontinence has been shown to be uncommon in men without any preexisting urethral trauma (~3%). Mock et al. (2013) reported a 19% incidence in patients with one previous TURP and up to 53% in those with a history of multiple procedures (although numbers were small).

Erectile Dysfunction and Management

As discussed earlier, with advances in radiation technology that can reduce incidental radiation doses to the bladder and rectum, radiation-associated GU and GI toxicity and impact on patient-reported outcomes have declined over time. However, the anatomic structure causing radiation-associated ED is not known. Published reports suggest that ED after radiation is caused predominantly by vascular damage, and some data suggest that dose to the penile bulb may be correlated with ED (DiBiase et al., 2000; Fisch et al., 2001; Merrick et al., 2001; Roach et al., 2000).

Patients in the Sanda study reported sexual dysfunction after RT (Sanda et al., 2008). By 24 months after treatment, 60% of patients reported poor erections (compared with 37% at baseline); however, decline in sexual function was mostly from patients who received radiation in combination with ADT, whereas sexual function decline was more modest in patients who received RT alone. Dess et al. (2018b) found similar results among 373 consecutive patients with localized prostate cancer who underwent SBRT, with 24- and 60-month potency preservation rates of 57% and 45%, respectively, among men with functional erections before therapy. Multivariate analysis of this population identified baseline health-related quality of life (HRQoL) and age as important factors at 24 months, and HRQoL and body mass index were significant predictors of erectile function at 60 months.

Potency preservation rates for patients undergoing brachytherapy alone appear superior to those reported for patients receiving prostatectomy, EBRT, or neoadjuvant hormonal therapy/EBRT/brachytherapy boost. Snyder et al. reported that 5 years after treatment, potency was maintained in 76% of patients undergoing brachytherapy compared with 71% receiving EBRT plus brachytherapy, and 58% in those undergoing EBRT, brachytherapy, and ADT (Snyder et al., 2012).

Potters et al. (2001) reported a 5-year potency maintenance rate of 76% with brachytherapy monotherapy and 56% with combined EBRT and brachytherapy boost. The addition of hormones to EBRT and brachytherapy boosted lower potency rates to 52%. Age was a significant prognostic factor in a univariate analysis (Merrick et al., 2002a), and the addition of EBRT and a history of diabetes mellitus were significant factors in a multivariate analysis (Robinson et al., 2002). In this meta-analysis, the probability of maintaining potency at 1 year after treatment was 76% (69% to 82%) with brachytherapy monotherapy and 60% (48% to 73%) with external beam and brachytherapy boost.

Sildenafil citrate and other phosphodiesterase type 5 inhibitors (PDE5Is) have been reported to be effective in 74% to 81% of patients who avail themselves of oral therapy for ED (Merrick et al., 2003; Raina et al., 2003). A study of 471 men who were treated with SBRT for localized prostate cancer found that sexual aids, primarily PDE5Is, showed efficacy at 5 years postradiation in 89% of men who found these aids helpful before radiation and 70% of previously aid-naïve patients (Dess et al., 2018a). This study also found that at 2 years, patients treated with radiation were significantly less likely than patients treated with prostatectomy to have tried non-PDE5I sexual aids including the Medicated Urethral System for Erection (3% vs. 15%), penile injections (3% vs. 14%), and vacuum device (5% vs. 19%). However, it is not clear if this reflected a difference in intervention utilization among radiation oncologists as compared with urologists or a difference in the prevalence of sexual dysfunction.

Key Points: Treatment Morbidity and Quality-of-Life Outcomes

- Most rectal bleeding that occurs after RT is mild and self-limited, or manageable with suppositories or enemas.
- Recently developed rectal sparing strategies such as injectable hydrogel can reduce the risk for radiation proctitis.
- Urinary incontinence is uncommon after either EBRT or brachytherapy.
- PDE5Is are frequently effective in patients who experience post-RT ED.

Evaluating the Response to Radiation Therapy

Prostate-Specific Antigen Follow-up: Definition of Failure

Serum PSA is widely accepted as a surrogate end point for monitoring the success of definitive treatment for localized prostate cancer. The PSA-based definition of biochemical failure after RT has evolved over time. Unlike RP, residual benign glands may be responsible for a low level of PSA production after RT, but an "acceptable" PSA level after successful RT is markedly lower than the range of normal for an age-matched population because of atrophy of nonmalignant acini (Grignon, 1995).

Ablation of normal prostatic epithelium is dose dependent. Median PSA nadirs range from 0.6 ng/mL after 70 Gy, to 0.3 ng/mL for radiation doses of 79 Gy, to 0.1 ng/mL or less for those receiving EBRT and a brachytherapy boost (Roach et al., 2006). **Nadir PSA** value is a significant predictor of outcome, but no absolute nadir threshold can or should be used to define cure (DeWitt et al., 2003). Although a standard definition of failure is essential for the purposes of clinical trials and reporting of data, it must be emphasized that establishing that a patient meets the criteria for biochemical failure is not justification for intervention.

Historically, the 1996 ASTRO Consensus Conference proposed the initial standardized definition of biochemical failure after RT (Roach et al., 2006). Recognizing that PSA stability after the nadir is important, the panel proposed to define failure as three consecutive increases in PSA, with "backdating" of such failure to a date midway between the nadir and the first increase. Although the ASTRO definition provided uniformity in reporting of results, it became clear with additional data that it was not an ideal solution to the problem of defining biochemical failure after RT. Waiting for three rises delayed the establishment of failure by 18 months or more (Cherullo et al., 2002); also, backdating biased the Kaplan-Meier estimate, an effect that was worse with shorter follow-up. In addition, the original ASTRO consensus definition of biochemical failure was not predictive of clinical progression or survival and was not developed using data from patients treated with combined radiation and ADT or those treated with brachytherapy.

To address these issues, a second consensus conference was held in Phoenix, Arizona, in 2005, and recommended that the standard definition of **biochemical failure after RT,** with or without short-term ADT, be established as a rise of 2 ng/mL or more above the nadir. This definition is known as the **“Phoenix”** or **“nadir + 2”** definition. This was informed by prior studies that compared various definitions and found that the nadir + 2 ng/mL definition best correlated with clinical local and distant relapse (Pickles et al., 2003; Thames et al., 2003). Instead of being backdated, failure is defined as occurring when the nadir + 2 ng/mL threshold is reached. Also, if salvage treatment is instituted before meeting the nadir + 2 ng/mL criteria, failure is considered to have occurred at the time of initiation of salvage treatment. PSA rises that can be clearly attributed to other causes, such as laboratory error, prostatitis that responds to antibiotics, or a benign PSA “bounce” that resolves without any intervention, should not be declared as biochemical failures (Horwitz et al., 2006). Kupelian et al. showed that adherence to the Phoenix definition resulted in apparent biochemical recurrence–free survival rates that were higher at 5 years but lower at 10 years compared with the original ASTRO definition (Kupelian et al, 2006).

Significance of Time to Nadir

Serum PSA declines slowly after completion of RT when ADT is not used. The manner in which PSA nadir and time to nadir reflect the type of failure requires explanation. Three sources of PSA potentially contribute to the nadir: residual benign prostatic epithelium, residual local prostate cancer cells, and subclinical disseminated micrometastases. The longer the time to nadir and the lower the absolute nadir, the more likely it is that only benign prostatic epithelium remains, hence the NED status. A higher radiation dose achieves a more complete ablation of normal epithelium and thus a lower nadir. For patients in whom RT fails to eradicate all the local tumor, the PSA declines progressively until the rate of growth of the surviving prostate cancer cells is greater than the death rate of those fatally damaged by the radiation, at which point the PSA begins to rise, generally relatively slowly. In the third scenario, subclinical micrometastases continue to grow unchecked despite successful treatment of the primary tumor. This growth rate outstrips the rate of decline in the local tumor population relatively early after treatment, leading to a higher and earlier nadir and a more rapid doubling time.

Both the level and timing of the nadir have correlated with distant metastases and disease-specific survival (Hanlon et al., 2002; Pollack et al., 2002a). Lee et al. (1996) reported that 75% of men whose PSA reached nadir in less than 12 months had distant metastases by 5 years, compared with 25% of those whose PSA took more than 12 months to reach a nadir ($P < .001$). Denham et al. (2008) analyzed the results of the TROG 96.01 trial, which randomized men with locally advanced prostate cancer to 0, 3, or 6 months of ADT in combination with EBRT. Biochemical failure before 24 months was associated with lower disease-specific survival. Buyyounouski et al. (2008) identified 18 months as the cut point for time to nadir that was an optimal surrogate for disease-specific survival in a population of men who were treated with 3D-CRT. An interval to biochemical failure of less than 18 months was independently predictive of distant metastases ($P = .008$) and was the only predictor of disease-specific mortality ($P = .0003$). The actuarial 5-year distant metastatic rate for biochemical failure occurring before or after 18 months was 52% versus 20% ($P < .0001$), and the actuarial disease-specific mortality was 36% versus 6% ($P = .0001$).

The previous two reports were based either on “conventional” radiation doses (66 Gy) or a range of doses. Kapadia et al. (2012) studied the interval to biochemical failure in a population of patients treated with dose-escalated RT in the range of 76 to 78 Gy, with or without ADT. Biochemical failure occurring before 18 months (short interval) predicted decreased disease-specific survival ($P <.0001$) and overall survival ($P < .0001$). Overall survival at 8 years was 87% for those with a long interval to biochemical failure, whereas it was 38% with a short interval to biochemical failure (HR 3.7). On multivariate analysis, biochemical failure before 18 months increased the risk for prostate cancer death and all-cause mortality, whereas biochemical failure after 18 months did not.

Significance of Nadir Value and Doubling Time

The level of PSA nadir achieved reflects the dose of radiation and the type of failure. With conventional-dose RT (~66 to 72 Gy), the median PSA nadir for patients with no evidence of disease (NED) in most series is 0.4 to 0.5 ng/mL (Critz et al., 1999; Crook et al., 2000; Zietman et al., 1996), whereas it is greater than 1.0 ng/mL for those with local failure and greater than 2 ng/mL for those with distant failure. Hanlon et al. (2004) reported that freedom from distant metastases was 96% for a nadir less than 1 ng/mL, 89% for nadirs 1.1 to 2 ng/mL, and 61% for nadirs greater than 2 ng/mL. Alcantara et al. (2007) evaluated patients who were treated with RT alone (median 76 Gy) and found that nadir PSA at 1 year independently predicted biochemical failure, distant metastasis, disease-specific mortality, and overall mortality. The 10-year distant metastasis rates for patients with a PSA nadir at 1 year of less than or equal to 2 ng/mL versus greater than 2 ng/mL were 4% and 19%, respectively ($P < 0.0001$). Zelefsky et al. (2009) analyzed patients who were treated with doses ranging from 64.8 to 81 Gy. A nadir less than 1.5 ng/mL at 2 years after treatment was predictive for long-term freedom from distant metastases and disease-specific mortality. The 10-year rates of distant metastases were 17.5% for men with nadirs greater than 1.5 ng/mL at 2 years compared with 7.9% for nadirs less than 1.5 ng/mL. In a stratified competing risks analysis, nadir PSA greater than 1.5 ng/mL at 2 years was an independent risk factor for distant metastases after adjusting for T stage, Gleason score, pre-RT PSA, and radiation dose ($P < .001$).

Royce et al. (2017) evaluated the performance of several candidate surrogates for all-cause mortality in men with unfavorable-risk prostate cancer and no or minimal medical comorbidities treated with radiation (70.2 Gy using 3D-conformal technique) with or without 6 months of ADT. They found that PSA nadir greater than 0.5 ng/mL predicted age-adjusted all-cause mortality (adjusted HR 1.72; 95% CI, 1.17 to 2.52; $P = 0.01$).

For patients treated with permanent seed brachytherapy, Grimm et al. (2001) found that the lower the PSA nadir, the higher the probability of long-term success. A PSA nadir less than 0.5 ng/mL is associated with significantly better long-term freedom from biochemical failure (95.2% vs. 71.5%) (Ko et al., 2012). PSA level at 5 years after brachytherapy is highly predictive of outcome, with 97.4% 10-year biochemical control in men with PSA less than 0.2 ng/mL at 5 years after brachytherapy. Hayden et al. (2010) found only one late biochemical relapse among 762 patients with a PSA less than 0.2 ng/mL at 4 to 5 years after implant.

PSA nadir and time to nadir differ after brachytherapy compared with EBRT. Crook et al. (2011) reported that if a mean ^{125}I dose to 90% of the prostate (D90) of 160 Gy is achieved, only 10% of such patients have a PSA level greater than 0.2 ng/mL at 5 years, with two-thirds of these patients still showing a decreasing trend. These results are very similar to observations by Stock et al. (2009) in which only 10.9% of brachytherapy-treated patients had a PSA level greater than 0.2 ng/mL at 5 years. The 10-year freedom from biochemical failure was 98%

for a 5-year PSA level less than 0.2 and 81% for a PSA level greater than 0.2 ng/mL. Grimm et al. (2001) reported that the proportion of patients with a PSA level less than 0.2 ng/mL continues to increase for up to 7 to 8 years. Freiberger et al. (2017) compared patients receiving brachytherapy +/– EBRT versus EBRT alone, and found that patients reached a mean nadir of 0.05 ng/mL when treated with LDR-BT and a mean nadir of 0.1 ng/mL after HDR-BT + EBRT. Both were significantly lower in comparison to patients treated with EBRT alone, who achieved mean nadir of 0.52 ng/mL ($P < 0.01$). Mean time to nadir was 32 months after LDR-BT, 31 months after HDR-BT + EBRT, and 19 months after EBRT.

The **postnadir doubling time** of the PSA level also correlates with the type of failure, with distant failures having shorter PSA doubling times of 3 to 6 months, whereas doubling times for those with local failures are 1 year or more. D'Amico et al. (2003) reported that a PSA doubling time of less than 3 months is associated with prostate cancer mortality. Valicenti et al. (2006) focused on PSA doubling time in an analysis of RTOG trial 92-02, which randomized men with locally advanced prostate cancer to 65 to 70 Gy of EBRT and short-term ADT plus or minus 24 months of adjuvant ADT. At 5 years, the actuarial disease-specific survival was 84.7% in the cohort of patients with a PSA doubling time of less than 12 months, compared with 94.3% for longer doubling times (HR 5.63, 95% CI, 3.78 to 8.3). PSA doubling time was significantly associated with disease-specific survival. Denham et al. (2008), in the analysis of the previously mentioned TROG 96.01 trial, used a cut point of PSA doubling time of less than 12 months. For these patients, the HR for prostate cancer death was 23.49 (CI, 12.94 to 42.63, $P < .001$).

Early surrogates such as PSA doubling time may help guide management of individual patients, suggesting earlier intervention in those with a PSA doubling time of less than 12 months while increasing the comfort level with continued observation in those with longer doubling times. Doubling time, however, may not be an ideal surrogate end point. The calculation of doubling time depends on the number of values available, being more reliable with a wide range of values (Denham et al., 2008).

Brachytherapy and the Benign Bounce Phenomenon

Benign PSA bounces or spikes are a well-recognized phenomenon after prostate brachytherapy. A spike or bounce is most frequently defined as a rise greater than 0.2 ng/mL followed by a durable decline (Critz et al., 2000) and is seen after both LDR and HDR brachytherapy. Overall, approximately 35% of men will experience a **PSA bounce** of 0.2 ng/mL or greater after LDR brachytherapy (Caloglu et al., 2011; Ciezki et al., 2006; Critz et al., 2000; Hinnen et al., 2012; Merrick et al., 2002b; Mitchell et al., 2008; Toledano et al., 2006), but in younger men the frequency may reach 65% (Gómez-Iturriaga Piña et al., 2010). The mean increase is 1 ng/mL but can be up to 10 ng/mL. Bounces may last as long as 12 to 18 months, and double peaks can be seen. Freiberger et al. (2017) studied 295 patients with localized prostate cancer, of whom 160 received brachytherapy either alone or in combination with EBRT, and found that PSA bounce was associated with significant improvements in 10-year biochemical control (83% vs. 34%, $P < 0.01$) and overall survival (82% vs. 59%, $P < 0.01$) as compared with patients who did not experience this phenomenon. Biopsies performed to investigate the rising PSA may show residual cancer with treatment effect (i.e., indeterminate) (Reed et al., 2003). Currently, there is no reliable way to discern whether a rising PSA in the first 3 years after brachytherapy represents treatment failure. Kirilova et al. (2011) investigated patients undergoing a PSA bounce with magnetic resonance spectroscopy and reported a diffuse increase in the ratio of choline to citrate across the gland, rather than the focal phenomenon that might be expected if the PSA increase were associated with tumor activity. It is recommended that a rising PSA within 30 months of brachytherapy be simply monitored. If the rise approaches 10 ng/mL, systemic staging is warranted, and, if the bounce persists beyond 30 months, a prostate biopsy is warranted. Only patience and careful follow-up demonstrate the subsequent spontaneous PSA decline to low levels.

Biochemical Failure and Impact of Neoadjuvant Hormones

When neoadjuvant ADT is used before RT, patients often start RT with an already undetectable PSA. If the PSA remains undetectable, it is impossible to determine a true nadir or time to nadir. A substantial proportion of patients treated with EBRT and ADT experience a PSA increase when the testosterone recovers. Zietman et al. (2005a) reported that the median time to PSA bounce (defined as an increase of 0.2 ng/mL) after EBRT (68.4 to 72 Gy) and ADT was 2.2 years. The median magnitude was 0.9 ng/mL, and 18.6% met the ASTRO nadir + 2 definition of failure. Subsequently, as the effect of the RT continues, the PSA declines once again. Based on a data set of 1865 men treated with EBRT, Pickles et al. (2006) reported a bounce duration of 12.5 months and a median height of 0.8 ng/mL, but only 2.1% met the nadir + 2 definition of failure. Interestingly, only 20% of bounces occurred during the testosterone recovery period, with the rest occurring once the testosterone had normalized. This may represent a delayed response to testosterone stimulation or may implicate other causes such as inflammation or instrumentation. Closer follow-up and more frequent PSA testing is more likely to detect PSA fluctuations or bounces. The Phoenix (i.e., nadir + 2) definition of failure is associated with fewer false calls of failure than the original ASTRO consensus definition of 3 rises after the nadir.

Post–Radiation Therapy Imaging

PSA measurement remains the standard for monitoring treatment response after RT. Although clinical trials to better understand the changes seen on MRI after RT and to evaluate the predictive value of postradiation MRI with regard to local recurrence are ongoing (e.g., the NCI-based NCT01834001 and MSKCC-based NCT02312401), it is not yet clear how this information should guide management after treatment.

The American Urological Association (AUA) has recognized the value of multiparametric magnetic resonance imaging (mpMRI) in the detection of recurrent prostate cancer in the setting of biochemical recurrence (Fulgham et al., 2017). mpMRI is recommended for men with a rising PSA after definitive prostate cancer treatment after a negative standard biopsy as it has been shown to improve biopsy positivity when a lesion is identified as compared with TRUS-guided prostatic fossa biopsy alone. With regard to routine follow-up after treatment, however, PSA remains the AUA-recommended test, and there is no clear role for follow-up imaging in the absence of PSA elevation.

The ACR Appropriateness Criteria identifies MRI of pelvis with and without intravenous contrast as “Usually Appropriate” for post-treatment follow-up of prostate cancer after RP if clinical concern for residual or recurrent disease is present (Casalino et al., 2011). In postradiation biochemical recurrence, however, radionuclide bone scan is recommended as the initial imaging with no further evaluation necessary for a positive scan. CT and MRI are reserved for patients with a negative or inconclusive radionuclide bone scan to evaluate for nodal enlargement or distant metastases. Again, there is no indication per these guidelines for routine follow-up imaging after definitive management.

Post–Radiation Therapy Biopsy, Timing, and Interpretation

Although serum PSA nadir has been widely adopted as a surrogate end point to determine treatment efficacy, it cannot distinguish between local and systemic failure. Post-RT prostate biopsies are a logical means of evaluating the local effect of RT. The major issues involve timing of the biopsies with respect to completion of RT, interpretation of indeterminate biopsies that show marked radiation effect, and the uncertainty imposed by sampling error.

In early reports, little was understood about the rate of histologic clearance of irradiated tumor, and failures were declared as early as 6 months after completion of RT (Scardino and Wheeler, 1985). It is now recognized that the time for histologic resolution of tumor parallels the time to serum PSA nadir and for the same reasons. Radiation causes postmitotic cell death, and fatally damaged cells may survive a limited number of cell divisions (Mostofi et al., 1992, 1993). Biopsies performed before histologic resolution is complete show a moderate-to-marked radiation effect (Crook et al., 1997). The ultimate viability of these cells cannot be predicted. Crook et al. (1995) determined that the optimal time to biopsy is 30 to 36 months after RT to allow histologic resolution of postmitotic cell death.

Gleason scoring of irradiated prostate cancer should be performed only if the histologic evidence of radiation effect is absent or minimal. Gleason's original work was based on surgically obtained material that had not been exposed to prior RT or hormonal therapy. It is based on gland architecture, which is known to be markedly altered by RT. Inappropriate application of the Gleason scoring system to disintegrating malignant glands showing a marked RT effect (Grignon and Sakr, 1995; Siders and Lee, 1992) results in a **false-positive biopsy** often misinterpreted as high grade and may lead to unnecessary salvage therapy (Reed et al., 2003). Along this same vein, most prostate adenocarcinomas treated with ADT resemble Gleason 4 or 5 tumors, further complicating the interpretation of post-treatment biopsies (Bostwick and Meiers, 2007).

Radiation atypia in benign glands can be severe enough to mimic malignancy (Bostwick et al., 1982; Cheng et al., 1999; Grignon, 1995). Anticytokeratin monoclonal antibody for high-molecular-weight keratin labels the basal cell layer of benign glands and therefore helps distinguish radiation atypia in benign glands from residual tumor where the basal cell layer would be absent (Brawer et al., 1989).

Scoring systems for the degree of radiation effect have been proposed (Böcking and Auffermann, 1987; Dhom and Degro, 1982) on the basis of cytoplasmic and nuclear changes (Box 157.1) and can be helpful in interpreting the biopsy (Crook et al., 1997). Their importance is to emphasize the need to differentiate between biopsies showing no or minimal radiation effect and those showing marked treatment effect (Zelefsky et al., 2004). Failure to recognize these differences dilutes the prognostic significance of biopsy status and may lead to inappropriate salvage therapy. Immunohistochemical stains for markers of cellular proliferation associated with subsequent failure such as proliferative cell nuclear antigen (Crook et al., 1994; Ljung et al., 1996) and Ki-67 have been used in interpretation of the significance of residual tumor (Crook et al., 2000).

Box 157.1

Grading Scheme for Cytoplasmic and Nuclear Radiation Effect[a]

Cytoplasmic Changes

0: No identifiable RT effect
1: Swelling and microvesicular change
2: Extensive vacuolation, macrovesicular change, and voluminous cytoplasm
3: Indistinct or ruptured cytoplasm
or
Lipofuscin pigment accumulation
or
Glands dilated or just single cells with no glandular formation

Nuclear Changes

0: No identifiable RT effect
Some swelling or smudging of nuclei but nucleoli still visible
or

Smudged and distorted chromatin
or
Nucleoli rare or absent
or
Large bizarre nuclei
or
Pyknotic small condensed nuclei

RT, radiation therapy.

---

[a] The scores for cytoplasmic and nuclear changes are added together. A score of 5 to 6 represents marked treatment effect, 3 to 4 is moderate, and 0 to 2 is minimal.

Zelefsky et al. (2008b) studied men treated with 3D-CRT with a median follow-up of 10 years. The 2-year biopsy status was strongly predictive of 10-year biochemical NED rate, freedom from distant metastases ($P = .004$), and disease-specific survival ($P = .007$). Importantly, patients with biopsies with marked treatment effect behaved as negative. This was confirmed by Crook et al. (2009) in a report on men who participated in a randomized trial of 3 versus 8 months of ADT before conventional EBRT. Biopsies were performed between 24 and 30 months after completion of RT. In multivariate analysis, biopsy status ($P < .0001$) and Gleason score ($P < .0001$) were the two strongest determinants of biochemical disease–free survival.

Imaging and Sampling Error

TRUS alone is of limited diagnostic use after RT because the increase in fibrosis alters the echogenic characteristics of the irradiated prostate (Crook et al., 1993; Svetec et al., 1998). MRI offers vastly improved soft tissue definition over either CT or ultrasonography, and mpMRI has greater accuracy in the detection of recurrent prostate cancer after RT than T2-weighted imaging alone. Westphalen et al. (2010) reported that the addition of magnetic resonance spectroscopy to T2-weighted imaging in men with suspected recurrence after EBRT increased the area under the receiver operating curve (AUC) to 0.79 from 0.67, detecting recurrence in 37 of 64 men. Donati et al. (2013) compared T2-weighted imaging to T2 with the addition of diffusion weighting (DW) and DCE and found that

T2-weighted imaging with DW improved the AUC for two independent readers but that DCE offered no additional benefit in a study of 53 men with suspected recurrence. Arrayeh et al. (2012) reported that pre-RT and post-RT endorectal 1.5-T MRI scans in 9 men with local recurrence were able to image the recurrence at the same site as the original dominant nodule, confirmed on whole-mount step-sectioned salvage prostatectomy. Although computational fusion of images from prior MRI acquisitions to inform TRUS-guided biopsy is now well established, several groups (Ménard et al., 2015; Penzkofer et al., 2015) have demonstrated the safety and efficacy of in-bore MRI-guided prostate biopsy.

Key Points: Evaluating the Response to Radiation Therapy

- Local therapy should be evaluated in terms of local tumor eradication. Local failures can be reduced by treatment refinements such as dose escalation and improvements in treatment planning and delivery.
- PSA nadir value and time to PSA nadir are associated with long-term outcome. Lower nadir values and longer time to nadir are favorable predictors of disease control.
- Benign PSA bounces most commonly occur after brachytherapy, and also occur after ADT + RT.
- Post-RT prostate biopsies are fraught with problems of timing, interpretation, and sampling error. mpMRI is a promising advance in the investigation of patients with suspected recurrence and can be used to guide confirmatory biopsies. Clearly viable residual tumor should be in evidence before considering radical local salvage for radiation failure.

Treatment Efficacy

Outcomes for External Beam Radiotherapy

The concept that higher radiation dose is associated with improved tumor control is a logical one, and is established from the earliest radiation experiments. The general applicability of the principle of **dose escalation** for prostate cancer was confirmed from the Patterns of Care studies performed in the 1980s. In these studies, patient treatment records were reviewed from 163 randomly selected radiation oncology departments located across the United States (Hanks et al., 1988; Leibel et al., 1984). Tumor control was better in patients who received higher doses of radiation to larger fields, albeit at the expense of increased complications. These studies sparked an intense interest in efforts to improve outcomes in men with prostate cancer by providing the best treatment-planning and delivery systems possible, and also by increasing the total dose given to the prostate (Leibel et al., 1994).

The improved effectiveness of higher-dose radiation for prostate cancer has been confirmed in six randomized trials (Table 157.8). In the MD Anderson Cancer Center trial, patients with low-, intermediate-, and high-risk prostate cancers were randomized to receive 70 or 78 Gy without ADT (Kuban et al., 2008). Higher radiation dose improved the 10-year freedom from failure rate from 50% (70 Gy) to 73% (78 Gy). The Proton Radiation Oncology Group (PROG) 95-09 trial randomized patients with low- and intermediate-risk prostate cancer to 70.2 or 79.2 Gy using a combination of conformal photon and proton radiation, without ADT (Zietman et al., 2005b, 2010). This trial also found a reduction in 10-year biochemical failure rates associated with higher radiation dose: 32.0% failure (low dose) versus 17.4% (high dose, $P < .001$). Subgroup analysis showed a benefit from higher dose applicable in both low- and intermediate-risk patients. A Dutch trial that randomized patients to 68 or 78 Gy included mostly high-risk prostate cancers (56%) (Al-Mamgani et al., 2008; Peeters et al., 2006). Approximately 21% to 22% of patients in each arm received 3 to 6 months of ADT per institutional practice. Higher-dose radiation demonstrated improved disease control: 7-year freedom from failure rates were 45% for 68 Gy versus 56% for 78 Gy ($P = .03$). Subgroup analysis found a benefit from higher-dose radiation for intermediate- and high-risk prostate cancers. A fourth trial by the MRC (RT01), which randomized patients to 64 or

74 Gy, differed from the others in that all patients received an LHRH agonist that started 3 to 6 months before and throughout RT (Dearnaley et al., 2007). This study included a mixture of low-risk (24%), intermediate-risk (32%), and high-risk (43%) patients. Again, high-dose radiation improved biochemical progression-free survival (60% vs. 71% at 5 years, $P < .001$). In subgroup analysis, the benefit of **dose escalation** was seen in all prostate cancer risk groups.

TABLE 157.8

Randomized Trials of Conventionally Fractionated Standard Dose vs. Dose-Escalated Radiation Therapy for Prostate Cancer

STUDY	MEDIAN FOLLOW-UP (YR)	PATIENT INCLUSION AND RISK (%)	RADIATION TECHNIQUE	TREATMENT ARMS	CA CO (%)

Taken together, these trials consistently demonstrated improved cancer control outcomes from higher-dose radiation that applied to prostate cancer patients in a variety of clinical settings including all risk groups and also with or without ADT. These trials provide level 1 evidence for the use of dose-escalated RT in prostate cancer, which is recommended as a standard of care by current guidelines (NCCN, 2016).

Although all six trials showed statistical improvements in biochemical control with dose-escalated RT, none were able to demonstrate an improvement in overall survival. In the MD Anderson trial, the observed reduction in biochemical failure was correlated with a reduced rate of distant metastasis, but this difference did not achieve statistical significance ($P = 0.059$). The largest trial, RTOG 01-26, was recently updated with an 8-year follow-up, but continues to show no improvement in overall survival (Michalski et al., 2018). The 8-year rates of overall survival were 76% with 79.2 Gy and 75% with 70.2 Gy (HR 1.00). The 8-year cumulative rates of distant metastases were slightly improved but again with borderline significance, at 4% for the 79.2-Gy arm and 6% for the 70.2-Gy arm (HR, 0.65; 95% CI, 0.42 to 1.01; $P = .05$). The high-dose arm had a lower rate of salvage therapy use. The reasons for this absence of survival benefit are likely due to the numerous and continually evolving salvage therapies available for men who have failed primary management.

Because modern RT (IMRT with image guidance as the standard) for prostate cancer looks nothing like RT from the 1990s (pre-CT era) or even early 2000s (pre-IMRT), review of the literature on the efficacy of RT must take into consideration type of radiation used and dose delivered.

Given that RT is a local treatment modality, the primary principle is to achieve local control, with the expectation that such control will prevent secondary dissemination beyond the prostate.

Role of Radiation Therapy in High-Risk or Locally Advanced Disease

Two major trials compared RT to conservative management in patients with high-risk disease, and demonstrated the ability of radiation treatment to improve survival in patients with prostate cancer. In both trials, patients were randomized to ADT with or without EBRT. In a multi-institutional trial sponsored by the National Cancer Institute of Canada (NCIC) and Medical Research Council UK (MRC) (NCIC CTG PR.3/MRC UK PR07), 1205 patients with high-risk or locally advanced prostate cancer were randomized from 1995 to 2005 to lifelong ADT (either bilateral orchiectomy or LHRH agonist) with or without RT to 65 to 69 Gy (Warde et al., 2011). The addition of RT significantly improved overall survival: 7-year survival was 66% for ADT versus 74% for ADT/RT ($P = .033$). In a Scandinavian trial (SPCG-7/SFUO-3), 875 patients with high-risk or locally advanced prostate cancer were randomized from 1996 to 2002 to lifelong ADT (3 months of combined androgen blockade followed by lifelong flutamide) with or without RT to a median of 70 Gy (Widmark et al., 2009). Again, RT decreased overall mortality: 10-year mortality was 39.4% for ADT versus 29.6% for ADT/RT ($P < .05$). These two trials show that RT improves overall survival in high-risk prostate cancer by an absolute magnitude of 8% (at 7 years) to 10% (at 10 years) compared with ADT alone. Of note, radiation doses used in the modern era for prostate cancer are much higher than those used in these trials and should be even more effective.

Key Points: Tumor Control After External Beam Radiotherapy

- EBRT improves overall survival compared with conservative management with ADT alone.
- At least six randomized trials have consistently shown that higher-dose radiation improves disease control. These studies have led to the current

standard of care, which is to use dose-escalated RT.

Outcomes for External Beam Hypofractionation

Although the evidence for prostate SBRT is still evolving, multiple phase III trials of moderate hypofractionation (Table 157.9) have been published.

TABLE 157.9

Randomized Trials of Moderate Hypofractionation

REFERENCE	N	MEDIAN FOLLOW-UP (Yr)	DOSE TOTAL (Gy) (FRACTION [Gy])	OUTCOME STANDARD VS. HYPOFRACTIONATION (%)	LATE TOXIC (%)
Lukka et al., 2005	936	5.7	66 (2) 52.5 (2.625)	5-yr FFBF,[a] 53 vs. 60 (NS)	Grade GI/GU, vs. 2 (

[a] Failure defined as three consecutive rises.

Prostate-specific antigen failure defined using nadir + 2 ng/mL except where marked.

BF, biochemical failure; *BRFS,* biochemical relapse–free survival; *CI,* confidence interval; *DFS,* disease-free survival; *FFBF,* free from biochemical failure; *GI,* gastrointestinal; *GU,* genitourinary; *HR,* hazard ratio; *NS,* not statistically significant; *RFS,* relapse-free survival; *yr,* years.
